are recoupled. Now, the dependence of the NMR spectral intensity with mixing time shows a dependence on the distance between the spin pairs, and hence the internuclear distance (r) can be determined. This approach has been used to determine ^{13}C spin pair distances to sub-nm resolution in membranes between neighbouring lipids, between lipids and proteins (Figure 8), within a ligand at informative sites to give the structure of ligand at its site of action in a membrane bound target and of a prosthetic group (retinal) in its binding site of a receptor.

Paramagnetic spectral broadening for a MAS NMR observed phosphate induced by a nitroxide spin-label, both at known positions in the primary sequence of membrane-bound bovine rhodopsin, a photoreceptor, has permitted some estimate of helix-loop distances to be made in the protein, supplementing other indirect structural details, even though the protein crystal structure is not available.

Membrane Dynamics

Both spin-lattice (T_1) and spin-spin (T_2) relaxation times give motional information about specific nuclei in a membrane system. Faster ($\tau_c \sim 10^7$ – 10^9 s) motions associated with acyl chain *trans*–*gauche* rotational isomerisms and protein residue motions affect T_1 values, whereas slower ($\tau_c \sim 10^3$ – 10^4 s) peptide backbone and membrane director fluctuations are inherently detected by T_2 values. Conventionally, high resolution NMR methods for measuring these relaxation times are used, the only difference being that broad spectral envelopes may show anisotropy in relaxation characteristics.

Membrane protein side chains (for example, Lys- $^6\text{CH}_2$; Val- $^7\text{CH}_3$) have been shown to possess fast (μs) motions from T_1 measurements of specifically deuterated residues in bacteriorhodopsin, even though the membrane environment was relatively rigid and crystalline. Similar approaches showed that the α -CH₃ group rotation is fast ($\tau_c \ll \mu\text{s}$) for membrane-bound, specifically deuterated retinal in the same protein, even at -60°C . Somewhat slower motions (in the ms range) occur in peptide backbones of membrane proteins.

An enhancement of the T_1 for cardiolipin phosphates through direct contact of the haem group in cytochrome c , a peripherally bound protein, suggests that this protein undergoes considerable conformational distortions (molten globule) when at the bilayer surface, on the 10^{-6} s time-scale, a feature of peripherally bound proteins which may be general.

Slow (ms) director fluctuations (wobbling around the membrane normal) are induced in bilayer membranes by proteins, as shown by measurements of T_2 . These motions are strongly coupled through the protein and membrane and may be significant in maintaining the protein in a dynamic equilibrium ready for function.

Figure 8 Rotational resonance ^{13}C MAS NMR has been used to determine both an intramolecular distance within a lipid and an intermolecular distance between a lipid and a protein in bilayers. A train of spectra are shown at different mixing times for the $n=2$ resonance condition at a spinning speed of 6248 ± 5 Hz, at two different temperatures, giving a distance (from an analysis of the intensity changes with mixing time) from the C1 on the *sn*-1 chain to the C2 on the *sn*-2 chain of 4.0–5.0 Å at -50°C in dipalmitoylphosphatidylcholine bilayers (a). To determine the intermolecular peptide–lipid distance, the spectral intensity changes due to magnetization transfer were determined under conditions of no magnetization transfer, that is, at off-resonance, (□), with unlabelled lipid to show the contribution from natural abundance (1.1%) ^{13}C , (■), and with ^{13}C -1,2-[2- ^{13}C] labelled lipid in bilayers containing glycophorin labelled at residue, ^{13}C -OH tyrosine-93 (●), to give a distance of 4.0–5.0 Å. Reproduced with permission from Smith SO, Hamilton J, Salmon A, and Bormann BJ (1994) Rotational resonance NMR determination of intra- and intermolecular distance constraints in dipalmitoylphosphatidylcholine bilayers. *Biochemistry* 33: 6327–6333.

Ligand Structure

Small molecules activate a range of cellular responses following binding to membrane-bound receptors. Solid-state NMR methods permit the structure and binding kinetics of such small ligands, using isotropic labelling to aid assignment and enhance sensitivity. The β -ionone ring orientation (6-*S trans* or 6-*S cis*) of ^{13}C -retinal in bacteriorhodopsin has been determined from direct

measurements using rotational resonance MAS NMR, by comparison with the known crystal structure of retinal. Deuterated retinal in bacteriorhodopsin and mammalian rhodopsin has been observed and the structural changes induced upon light incidence determined to good precision using an *ab initio* approach. ^{13}C -labelled retinal has proved particularly successful for use in describing sugar binding to sugar transporters, drug binding to P-type ATPases (H^+/K^+ -ATPase and Na^+/K^+ -ATPase) and

acetylcholine binding to the membrane-bound receptor. In the absence of crystals of this class of proteins at the present time, detailed structural information from solid-state NMR approaches and observation of a range of isotopes are helping to elucidate functional descriptions by this approach.

What Is Metabonomics in Food Science?

The term metabonomics has been established to describe a system approach used to examine the changes in the low-molecular weight metabolites in a biofluid or an intact biological tissue. The definition, proposed in the 1990s, expresses the quantitative measurement of the multivariate metabolic responses of multicellular systems to pathophysiological stimuli or genetic modification. This approach has been extensively demonstrated in the pharmaceutical and medical areas as invaluable, particularly if used in tandem with genomics and proteomics, to help describe the overall organism response to stimuli such as disease, toxic agents, or diet. Health-related metabonomics involves primarily the use of nuclear magnetic resonance (NMR) spectroscopy, with increasing relevance and usefulness of mass spectrometry (MS)-based methods, and multivariate analysis to establish a metabolite profile of the sample and, therefore, physiological state of the individual. The same principles may, however, be extended to food science in two different ways. First, by defining the metabolite profile (or metabolome) of a food product as its fingerprint and, thus, using it as a mirror of the state of the food (e.g., fresh or aged, adulterated, contaminated, and genetically modified (GM)). Second, by using biological biofluid or tissue metabonomics to explore the metabolic effects of particular foods, food components or food combinations, that is, to understand the global biochemical aspects of food when in interaction with the organism. This last approach is particularly important, for instance, for the well-informed development of new functional foods,

claimed to affect in a positive way certain metabolic pathways or effects.

NMR-based metabonomics is a new method in which NMR spectroscopy may be used for food quality control, following the first and very successful method of site-specific nuclear isotope fractionation (SNIF)-NMR. This is today extensively used in the wine industry, usually involving ^2H observation for the measurement of isotopic ratios and correlation with metabolite origins.

Samples, Tools, and Challenges in Food Metabonomics

Samples and Analytical Tools

The sample systems to be addressed are nearly always complex metabolite mixtures, their complexity arising from the high diversity in the nature of compounds and corresponding concentrations. In food metabonomics, food samples are usually analyzed in their intact state and may be presented in liquid or solid state. In nutritional metabonomics, the systems under analysis are biofluids or intact biological tissues. Following the metabonomics concept of simultaneous and rapid detection of multi-parameters (or metabolites), the tools to be chosen need to have the ability to measure many different types of compounds simultaneously, avoiding the traditional approach of selective extraction and concentration of single compounds and families of compounds. Besides being time consuming, the latter approach is nearly always targeted to a certain compound type, based on information collected previously. A distinct feature of metabonomics is that possible markers (whether new compounds or compound variations) are unknown a priori and thus any simplification or selection of the system to be studied should be avoided.

NMR spectroscopy and, increasingly, MS spectrometry (such as gas chromatography (GC)-MS and liquid chromatography (LC)-MS) have been selected as the main analytical tools to be employed for complex mixture analysis, due to their relatively high compound resolving power. This ability is particularly enhanced for NMR, whereas MS is more sensitive. The two analytical tools are, therefore, complementary and their tandem use usually enables further advances in compound identification. ^1H is the most used NMR-active nucleus for metabonomics studies due to its high sensitivity and natural abundance. **Figure 1** shows the high complexity of ^1H NMR spectra of some liquid foods, reflecting the

Figure 1 Typical 1D ^1H NMR spectra of (a) mango juice, (b) wine, and (c) beer. The expansions show the spectral detail in the low intensity aromatic region (spectra have a vertical cutoff to enable observation of minor peaks).

great wealth of compositional information contained in such spectra, each metabolite being characterized by a specific set of peaks.

In the case of solid or semisolid foods, a ^1H NMR spectrum of workable quality, in terms of compound assignment and multivariate analysis applicability, must be recorded using high-resolution magic angle spinning (HRMAS). MAS is a method derived from solid-state NMR, which leads to resolution improvement of the NMR signals due to the averaging out of anisotropic nuclei interactions that, otherwise, would lead to a broad featureless spectrum. In HRMAS probes, the MAS capability is coupled to high-resolution NMR characteristics, such as the use of a lock deuterium signal to stabilize the magnetic field within the sample, thus resulting in the recording of well-resolved spectra for solid foods.

Multivariate analysis of the collected data is of crucial importance for the outcome of metabonomic studies. Initially preferred methods such as principal component analysis (PCA) and partial least squares (PLS) analysis have gradually been used concomitantly with increasingly sophisticated new methods, mostly developed

in response to the needs of health metabonomics. For instance, the high variability of some biological samples due to random effects, such as diet, lifestyle, and genetic characteristics, may be filtered off by selective multivariate methods so that the effects of one particular controlled variable may be evaluated. This approach may also be of use in food metabonomics, for instance when random effects (e.g., short-term atmospheric changes) are expected to affect the food metabolome. Another example relates to small pH differences occurring between samples, which lead to small peak shifts and artifacts in multivariate analysis results, hence seriously hindering their interpretation. As a result, much attention has been given to the development of peak alignment methods to reduce the extent of this problem.

The Challenges

Once the systems to be investigated and the tools to be used have been identified, the challenges to overcome become clearly defined. First, the experimental profile of the food sample, viewed by either NMR or MS, must be

translated into a list of metabolites and their relative or absolute concentrations. NMR peak assignment involves the necessary use of two-dimensional NMR experiments that enable the unveiling of compound profiles within the overlapped spectral envelope. Using this approach in tandem with comparison of NMR profiles found in compound databases, enables the identification of many tens of metabolites in one single NMR spectrum. The compositional profile thus established should be reproduced for a group of samples chosen as controls for which such compositional profile may be confirmed and statistically validated. The resulting metabolite information can then be taken as the food metabonomic fingerprint, against which any changes occurring as a result of any type of perturbations may be measured. Second, a group of perturbed samples should be studied using a similar approach, with the compulsory requirement that any eventual variations in composition require adequate validation using multivariate analysis methods. In food sciences, adequate validation should be considered as a two-step process where chemometrics validation is carried out not only within the samples selected for a particular perturbation study (controls vs 'perturbed' foods), but also, and very importantly, in food metabonomics, based on inter-perturbation characteristics. For example, if the effects of genetic modification on the metabolome of a fruit is being studied, then it is necessary that such effects may be compared with those resulting from other main variables in the history of the fruit, such as soil and atmospheric conditions and cultivar. In this way, the specificity of the effects due to genetic modification may be suitably evaluated and their future for specific detection envisaged.

Food Metabonomic Studies

Studies of Liquid Foods

Table 1 shows the list of foods that have been studied with an NMR-based metabonomics approach, tackling issues as varied as adulteration, genetic modification, geographical or varietal origin, and manufacturing process.

Most of the studies listed in **Table 1** refer to the direct study of liquid foods, without selective extraction of components. An exception to this is tomato, with most studies focusing on extracts. Olive oil, with the most extensive set of studies and still of interest today, is at the top of the list in **Table 1**. It is followed by wine, fruit juices, and beer and, more recently, by preliminary studies of some other foods. In addition, the cases noted comprise solid foods (cheese, meat, flour dough, bread) that use ^1H HRMAS.

Olive oil

Owing to its great economic value, the olive oil case may be taken as a case study that demonstrates the use of NMR metabonomics to characterize olive oil and its

Table 1 List of foodstuffs studied by NMR-based metabonomics

Food	Number of studies	Year(s) of publication
Olive oil	16	1997–2008
Wine	8	2002–2007
Dairy products ^a	7	2003–2007

Coffee	2	1999–2002
Vinegar	1	2008
Meat ^a	1	2005
Flour and bread ^a	1	1998, 2003, 2007

^aThese studies include the use of high-resolution magic angle spinning (HRMAS) for solid food analysis.

^bThese studies usually focus on tomato extracts.

quality along several possible directions. Most studies focused on Italian olive oil and involved the use of ^1H NMR, although some employed ^{13}C NMR and ^{31}P NMR for selective phospholipids analysis.

The main adulteration issues regarding olive oil have been addressed, demonstrating the possibility of detecting addition of seed oils or nonedible oils, as well as distinguishing virgin from refined olive oil. However, the majority of the studies carried out have tackled the problem of identification of geographical origin and year of production, as these determine the expected overall quality and, therefore, the price of the product. Initial studies compared products from different country regions and, gradually, have moved on to addressing products from subregions, that is, aiming at a more fine and challenging product control. Generally, these studies identify minor components (e.g., aldehydes, terpenes, squalene, and beta-sitosterol) as having the highest specificity for product origin, and sample identification is usually successfully achieved. Furthermore, it was found that the contents of oleic and saturated fatty acids are strongly influenced by the irrigation practice, whereas the content of volatile compounds is sensitive to the altitude of the olive trees. **Figure 2** shows an example of sample classification from different sub-regions within the Italian province of Lazio, obtained by linear discriminant analysis (LDA).

With a view closer to potential routine industrial use, some work has used ^1H NMR in tandem with high-throughput automation reducing sample analysis time to 5 min per sample, and therefore enabling the analysis of 300 samples per day. Such studies lead to accessible analysis costs, an issue of paramount importance if routine use is to be considered.

Wine and beer

The metabonomic characterization of wine and beer was initiated in the early part of the twenty-first century and extends to the present.

Figure 2 Linear discriminant analysis (LDA) plot based on the intensities of selected peaks observed in the ^1H NMR spectra of olive oil samples from five political provinces of Lazio, Italy. The ellipses represent 95% confidence regions for each group. The ellipse is not reported for Latina olive oils, due to the small number of samples. Reprinted from D'Imperio M, Mannina L, Capitani D, et al. (2007) NMR and statistical study of olive oils from Lazio: A geographical, ecological and agronomic characterization. *Food Chemistry* 105: 1256–1267, with permission from Elsevier.

In the case of wine, the effects of several issues of importance for the composition and quality of wines on its metabolome have been addressed: plant variety, geographical origin of wine, year of vintage, and quantitation of specific components. Most of the studies have involved the direct analysis of wines, but a systematic study has compared the effects of different sample preparation methods on the results of NMR metabonomics. In wine, the role of amino acids seems determinantal for separation according to wine variety, whereas changes in components like glycerol, butylene glycol, and succinic acid are associated with geographical origin.

In addition to wine analysis, some work has been devoted to characterizing the metabolome of mature grape berries, originating from different wine-growing areas of France, as berry composition should relate directly to wine quality. A second interesting deviation from direct wine analysis has been the study of the compositional changes prompted by wine fermentation. Multivariate analysis of the ^1H NMR spectra collected for samples during fermentation enabled the monitoring of variations in different compounds simultaneously (ethanol, fructose, glucose, methanol, glycerol, malic acid, tartaric acid, succinic acid, acetic acid, and lactic acid), thus showing the promise of NMR metabonomics in wine-making process quality control. The same work has shown the use of signal integration to quantify these metabolites but, due to difficulties arising from peak overlap, an additional approach to quantitation has emerged and has been demonstrated on wine,

among other systems. This approach involves the use of multivariate analysis of the ^1H NMR spectra against the results of a known reference method such as infrared spectroscopy, capillary electrophoresis, or enzymatic tests. In the case of wine, quantitation of glycerol and malic acid was achieved by correlating the NMR spectra with the metabolite contents measured by infrared spectroscopy, using PLS as the multivariate analytical tool. The same study also addressed the issue of small pH discrepancies between samples and subsequent peak shifting. A method for signal alignment in selected spectral regions has been proposed and demonstrated for instance for the ethanol multiplet (Figure 3).

In the case of beer, studies have included issues such as classification by type and brand, production site and date, sensorial properties, and quantitation of selected metabolites. Similarly in the case of wine, attention has been given to the monitoring of the brewing process and results used to detect compositional deviations within different production site and dates. With the basis on the metabolite changes detected, the origin of such deviations may be pinpointed and addressed to yeast quality or changes in the malting and fermentation steps. Quantitation of key metabolites in beer, such as organic acids and amino acids, has also been carried out using PLS models to correlate the NMR dimension with results obtained by capillary electrophoresis and high performance liquid chromatography (HPLC), respectively.

Fruit juices

Some of the main variables affecting fruit juice quality are fruit cultivar, country of origin, degree of ripening, and adulteration. NMR metabonomics has addressed these factors in relation to different types of juices (e.g., orange, mango, apple, and grapefruit) and particular attention has been given to the main adulteration methods used in the orange juice industry. Methods such as pulp wash addition and mixture of juices from different fruits have been studied by NMR and multivariate analysis and these effects have proven to be detectable based on small changes in minor components and in many additional unidentified signals. This shows how the metabolome of the fruit and its juice is finely dependent on its history, carrying much information that is still poorly understood but may be potentially employed for quality control. In fact, the NMR metabonomics applications to fruit juices have, in 2008, developed into a routine application in the juice industry, thus demonstrating the real value of all remaining studies devoted to other food systems in becoming a routine industrial tool of great value in food quality control. The analytical model developed for fruit juices enables the rapid identification of metabolome deviations from the norm, for a particular type of juice, and looks for compound matches within a large compound database to rapidly identify and quantify the interfering metabolites. This

An exploratory study of ^1H NMR spectra of table wines. *Journal of Chemometrics* 20: 198–208, with permission from Wiley.

enables many different aspects of the juice history to be tracked back and monitored.

Tomato

Tomato has been selected as the first fruit for NMR metabonomic studies because it was the first genetically modified (GM) or transgenic food commercialized for direct consumption. The GM tomato has also triggered concerns related, for instance, to what other changes and effects may be induced by genetical modification on the fruit and, eventually, on the human organism.

NMR metabonomics has been used to compare the composition of GM and unmodified tomato, showing that the differences are statistically significant and dependent on a degree of fruit maturation (Figure 4); it has demonstrated that many additional compounds other than the intended ones result from genetic manipulation. The nature and physiological role of such compounds are still unknown but the results show how unselective the effects of genetic manipulation may indeed be. However, the authors of the report pointed out that the effects of tomato genetic manipulation still lack appropriate comparison with other compositional effects due to for instance soil and atmospheric variabilities. Only once this is established can an NMR metabonomics method be envisaged as a specific tool for GM effects.

Studies of Solid Foods

The direct analysis of solid, or semisolid, foods has been increasingly recognized as very valuable in that it rapidly

gives overall metabolomic information of the sample, avoiding sample dissolution and compound selection by separation procedures. The relatively slower developments in this area, compared to those involving liquid foods, are justified by issues such as the distinct instrumental requirements and related underdeveloped characteristics such as automation and quantitation. As mentioned earlier, the recording of well resolved and, therefore, informative NMR spectra of solid foods usually requires the use of the HRMAS technique that enables ^1H NMR spectra to be obtained with comparable resolution to that for liquid foods.

It has been found that minor components such as amino acids and specific fatty acids are determinantal in enabling the distinction between cheeses originating from different countries in Europe and from different subregions within the same country. This distinction becomes clear in a canonical analysis plot such as that shown in Figure 5.

Similar approaches have been followed for meat, flour dough, and bread. In these studies, ^1H HRMAS was employed, in tandem with isotope ratio measurements, showing that satisfactory sample classification is achieved according to geographical origin within the same country.

Nutritional Food Metabonomics

The use of NMR metabonomics for nutritional studies and, thus, advancing in the understanding of food–organism interaction involves the study of biofluids of

Figure 4 (a) First two Partial Least Squares (PLS) scores for 80 transgenic and control tomatoes at three stages of maturity and (b) PC1 and PC3 for 60 transgenic and control red tomatoes: ○, red transgenic; ●, red control; △, turning transgenic; ▲, turning controls; □, green transgenic; ■, green control. individuals subjected to selected well-controlled diets. This approach is, however, prone to the health-related metabonomic concerns such as, suitable subject training and diet control, group size, and a careful characterization of the control group. Initial studies along this direction have emerged in the past few years, as shown in **Table 2**.

The first studies of this kind have investigated the effects of soy isoflavones on the composition of blood plasma of healthy premenopausal women. Differences noted between lipoproteins, amino acids, and carbohydrates profiles have indicated that a soy-induced alteration in the energy metabolism takes place. Additional work has investigated the metabolic effects of chamomile ingestion, by noting an increase in hippurate and glycine levels and a decrease in creatinine level in urine. Interestingly, these effects were still present two weeks after chamomile intake. The metabolites of black and green tea upon human consumption have also been compared through both urine and plasma composition, with particular attention given to the metabolic role of tea flavonols.

More recent work has been carried out on the effects of milk and meat protein on the composition of urine and plasma of 8-year-olds and, therefore, on their metabolism. Results show that different animal proteins have different metabolic effects, viewed mainly by the compositional changes in the urine (**Figure 6**). The milk diet was seen to induce reduction in urinary excretion of hippurate, suggesting alterations in gut microflora. It is claimed that this information may be useful for further studies on the effects of bioactive components in milk.

Besides the studies on the metabolic effects of specific foods, a few other studies have been carried out on the effect of diet manipulation on the profile of human biofluids and, hence, metabolism (**Table 2**). A new concept has recently been put forward and named as nutrimentabonomics. This advances the challenging new idea that individuals are inherently characterized by a certain nutritional phenotype that determines their diet habits and preferences. This was based on a study of the metabolic phenotypes of subjects characterized by a

specific behavioral/psychological dietary preference, namely, ‘chocolate desiring’ or ‘chocolate indifferent,’ for whom differential metabolic biomarkers were found.

A View to the Future

Generally, the metabonomics work carried out on foods such as olive oil and fruit juices has clearly demonstrated the suitability of the NMR-based metabonomics method for routine, fast, industrial applications. This development requires that stumbling blocks such as pH effects and difficulties in quantitation and determination of the specificity of observed changes are tackled. In some cases, enlargement of sample universe and group size is of paramount importance to correctly evaluate the promise of a

particular application. Once appropriate economical and scientific developing conditions are found, such NMR-based metabonomic tools are nearly certain to be successful.

A parallel possible development relates to the inherently low sensitivity of NMR, and the subsequent interest in coupling it to more sensitive methods such as MS (for instance in the form of GC-MS). The use of sophisticated multivariate analysis methods may then be used to correlate the variations of metabolites in both domains, thus providing the building blocks of information on the bridge between more and less abundant compounds. This would be of extreme value in enabling more complete knowledge on food metabolomes to be built and higher understanding of food chemistry to be obtained. An additional outcome of the unbiased nature of this approach, of no lesser value, is the possibility of finding new products, some of which may be potentially important in a number of health applications.

Finally, a third avenue of developments, presently just emerging and starting to show its promise, is the use of NMR metabonomics for nutritional studies. This is particularly important if a well-informed development of new foods, including new functional foods, is to be carried out. However, this approach involves the study of biofluids of individuals subjected to selected well-controlled diets and, unlike food analysis that presents less constraints in terms of sample collection and group size, it is prone to concerns such as subject training and appropriate diet control.

v_n	ion velocities
V_{acc}	ion acceleration potential
w	peak width
W_h	width of energy-resolved metastable peak at fractional height h
W_m	width of the M_1^{*+} ion beam
α	$\ln 2$

Metastable Ions, Their Origins and Observation

Metastable ions are those that dissociate en route from an ion source, through a mass analyser to an ion detection device. That ions can dissociate in flight was recognized by Hipple and Condon in 1946 when they provided the explanation for the presence of the diffuse peaks that they had observed in normal, electron ionization (EI) mass spectra obtained with a single-focusing magnetic sector mass spectrometer. It should be emphasized that the term metastable refers only to ions that are able to fragment in flight by virtue of internal energy that they acquired within the ion source, not after acceleration therefrom, nor by collisions with a target gas, nor by radiative excitation as they traverse the apparatus. They are thus unimolecular dissociations.

It was the striking and varied phenomenology produced by metastable ions that made them of particular interest in the 1960s and 1970s, when many laboratories had magnetic sector (B) instruments or double-focusing mass spectrometers consisting of an electric sector (E) and a magnetic sector arranged BE or EB (tandem mass spectrometers). Much of this article will describe observations made with tandem mass spectrometers.

First, however, consider a simple magnetic sector instrument. Singly charged molecular or fragment ions leaving the ion source will all have the same translational energy,

$$eV_{acc} = \frac{1}{2}M_1v_1^2 = \frac{1}{2}M_2v_2^2 = \frac{1}{2}M_nv_n^2$$

independent of their mass M_n . The ion acceleration potential is V_{acc} and v_n are the ion velocities. As the magnetic analyser field strength is changed, ions of different mass will be transmitted to the detector giving rise to the normal mass spectrum, a series of sharp, well-defined signals for each m/z value for the ions present. If, however, an ion M_1^{*+} is metastable and fragments in flight

the fragment ion M_2^{+} will have less translational energy than an ion M_2^{+} produced in the ion source. The fragment ion's translational energy is $\frac{1}{2}M_2v_1^2$ and is equal to $\frac{1}{2}(M_2^2)v_2^2$ given that for source ions $\frac{1}{2}M_1v_1^2 = \frac{1}{2}M_2v_2^2$. The fragment ion M_2^{+} from metastable M_1^{*+} will thus appear in the normal mass spectrum at an apparent mass (M_2^2/M_1) .

For sector mass spectrometers, V_{acc} is typically 2–10 kV and the timescale for ions to pass from ion source to detector is typically in the range 5–50 μ s for ions of $m/z \sim 100$.

The signals at (M_2^2/M_1) were observed in the majority of cases to be much wider than those of normal fragment ions and were typically of Gaussian profile.

Note that the presence of these diffuse peaks at nonintegral m/z values provides the observer with direct proof that a given fragmentation has indeed taken place, e.g.

This metastable dissociation of C_5H_5^{+} ions will produce a peak at apparent mass 23.4 Da. Clearly these phenomena can (and do) assist in the interpretation of mass spectra by unequivocally linking a fragment ion with a specific precursor.

The reason for the diffuse shape, i.e. Gaussian profile, of metastable peaks is that upon dissociation a fraction of the internal energy of M_1^{*+} is converted into translational degrees of freedom of the products M_2^{+} and M_3^{+} . This

kinetic energy is released isotropically and results in the broadening of the metastable peak relative to the width of a beam of undissociating ions from the source. In a tandem mass spectrometer of BE geometry, under conditions of good energy resolution, the shape of a metastable peak may be examined in detail and physicochemical information derived therefrom. In such a tandem mass spectrometer (shown in **Figure 1**) the electromagnet (B) is used to select an ion M_1^{*+} of interest. Under normal operating conditions the electric sector potential (E_s) is set to transmit all the ions from the ion source. If, however, M_1^{*+} is metastable during its flight through the (second) field-free region between the two analysers, the fragment ion M_n^{*+} (or ions) will only be transmitted through the electric sector if its potential is reduced in the ratio $M_n(E_s)/M_1$. Scanning this potential from zero to E_s will transmit all fragments from metastable M_1^{*+} ions at appropriate $M_n(E_s)/M_1$ values. Such a spectrum is known as a mass-selected-ion kinetic energy spectrum (MIKE).

Metastable Peak Shapes and Their Significance: Kinetic Energy Release

As stated above, the majority of metastable peaks have a Gaussian-type profile (**Figure 2a**). Indeed many peaks can be described by a simple variant of the Gaussian formula, $b = \exp(-\alpha\omega^2)$ (where b is the fraction of the peak height at which the width, ω , is measured and $\alpha = \ln 2$) where the index 2 is replaced by n , taking on a range of values from about 1.4 to 2.1. Note that the distribution of released energies derived from the exact Gaussian function is Maxwell-Boltzmann in form.

A second class of peak shapes are the so-called flat-topped or 'dished' metastable peaks (**Figure 2b**). The dish in such peaks is instrument-dependent and arises from the magnitude of the kinetic energy release (KER) and its distribution (see below). As the peak is recorded by sweeping the electric sector voltage over the

appropriate range, all fragment ions having large components of translational energy released in the x - and y -axial directions (see **Figure 1**) will be recorded. Those having large z -axial components may, however, be unable to pass the collector slit because of its finite height. These 'lost' ions result in the observed dish. The effect is only important for dissociations in which the magnitude of the KER is large (see below).

The relationship between the metastable peak characteristics and the magnitude of the KER (T_b) is given by

$$T_b = \frac{M_1^2}{16M_2M_3E_s}(W_b^2 - W_m^2)$$

where W_b is the width of the energy-resolved metastable peak at fractional height b , measured in electric sector volts; W_m is the corresponding width of the M_1^{*+} ion beam (also in sector volts). It has become customary to report KER values corresponding to half-height peak widths, $T_{0.5}$; they are usually given in meV. Under good energy-resolution conditions

$$\frac{W_{m(0.5)}}{W_{0.5}} < 0.1$$

making the main beam correction small to negligible.

For Gaussian-type peaks, $T_{0.5}$ values lie in the range 0–50 meV, while for flat-topped peaks, $T_{0.5}$ is from ~200 meV to several volts.

It is believed that the great majority of Gaussian-type metastable peaks arise from ion fragmentations with no reverse energy barrier, E_{rev} (**Figure 3**), whereas flat-topped peaks are associated with a finite or large E_{rev} . This is also illustrated in **Figure 3**. The origin of the KER for the Gaussian peak is the excess energy, $E^\ddagger$, above the threshold for the fragmentation necessary to achieve the rate constant (k) for the process; typically k is $\sim 10^5 \text{ s}^{-1}$. For the dissociation with the reverse energy barrier, E_{rev} (a fixed energy) is augmented by $E^\ddagger$ (sometimes referred to as the nonfixed energy).

Figure 1 Schematic drawing of a tandem mass spectrometer of BE geometry.

Figure 2 Simple Gaussian (a) and 'dished' (b) metastable peaks. For comparison a typical profile for an undissociating ion beam is shown between them.

Figure 3 Potential energy profiles for ion fragmentations giving rise to Gaussian and flat-topped metastable peaks.

The range of rate constants (k) accessed in the metastable time frame is easily calculated using the first-order rate equation. Direct experimental measurements of the way in which a fragmentation's rate varies with internal energy (E) are made by 'photoelectron photoion coincidence' methods. A typical plot of $\ln k$ vs. ϵ curves with the metastable ion window included is shown in **Figure 4**. In general, the fraction of $E^\ddagger$ that is released as translational energy is small, about 3–10%. For dished peaks, much larger fractions of E_{rev} may be released.

Composite metastable peaks are also known and these can arise from the following situations:

- A single ion structure M_1^{*+} , dissociates metastably via two competing reactions to give isomeric fragment ions.

Figure 4 $\log k$ vs. ϵ curves for the dissociation of the phenyl halides $\text{C}_6\text{H}_5\text{X}^+ \rightarrow \text{C}_6\text{H}_5^+ + \text{X}^\bullet$. The metastable ion window is shown as $P(M^*)$. This curve represents the probability that an ion having the corresponding dissociation rate constant, k , will fragment in the metastable ion time-frame, here $\sim 1\text{--}3\ \mu\text{s}$. At the maximum, about 11% of the beam is dissociating.

- A given ion M_1^{*+} , has two stable isomeric forms (in an ion source) which metastably fragment via different transition states either to give fragment ions of different structure or to give fragment ions having only one structure.

Two examples are shown in **Figure 5**.

Collision-Induced Dissociations

The early experiments on collision-induced dissociations (CID) were performed using sector instruments such as

Figure 5 Composite metastable peaks. (a) Peak for C_3H_5^+ (m/z 41) ions dissociating to give isomeric fragment ions C_3H_3^+ (m/z 39). The broad signal corresponds to the production of the cyclopropenium cation, while the narrower component is for the generation of the propargyl isomer $[\text{HCCCH}_2]^+$. (b) Signal for isomeric C_4H_9^+ ions, fragmenting via different transition states, to produce by methane loss the 2-propenyl cation, $[\text{CH}_3^+\text{CCH}_2]$ (not the thermochemically more stable allyl isomer $[\text{CH}_2\text{CHCH}_2]^+$).

that shown in **Figure 1**. A small constricted region or cell within the second field-free region close to the ion beam focus, with a diffusion pump placed thereunder, has a target gas admitted to it. The differential pumping of the region is such that very little gas diffuses into the high-vacuum region outside the cell. The cell, 2–3 cm long, is only a small zone within the second field-free region, ~ 1 m long. When sufficient gas has been admitted to reduce the intensity of the mass-selected ion beam by 10% (a condition corresponding to predominantly single collisions) the ion kinetic energy spectrum is recorded. Unlike the metastable-ion (MI) mass spectrum, the CID mass spectrum contains many signals and is similar in appearance to the normal mass spectrum of $M_1^{+\bullet}$ (with M_1 being a stable neutral molecule).

The peaks in this CID mass spectrum are all broadened by kinetic energy release, making the spectrum rather poorly resolved. Nevertheless, as described elsewhere, the CID mass spectrum can be used as an invaluable tool in ion structure assignments. If a charge of say 500 V is placed on the collision cell (necessitating its electrical isolation from the apparatus), then MI and CID peaks may be separated. MI peaks remain undisplaced, whereas all CID peaks are shifted to higher energy (positive charge) or lower energy (negative charge).

Note that poor background pressures in the field-free regions can lead to unwanted CID contributions to MI mass spectra. In general, more than four peaks in an MI mass spectrum may be regarded as showing possible high vacuum failure. A consideration of the likely energy requirements for the observed fragmentations may also help to resolve this problem.

Metastable Ions and Ion Structures

In the mid-1960s the first semiquantitative relationship between metastable-peak intensities and the structure of

a fragmenting ion was proposed. This so-called ‘metastable-peak abundance-ratio test’ was based on the premise that when two (or more) competing fragmentations from the same ion give reasonably intense metastable peaks, then the ratio of their abundances may be used as a criterion for ion structure. Thus, if dissociating ions of a given molecular formula and m/z ratio, derived from a variety of precursor species, all display the same metastable peaks having similar relative abundances, then it can reasonably (but tentatively) be concluded that the fragmenting ions have the same structure. It is also possible that the fragmenting species consist of mixtures of common composition but having different structures.

The chief problem with this simple criterion was to decide what constitutes a ‘significant’ variation in metastable peak abundances. Indeed it was quickly realized that the ratio will be susceptible to the distribution of internal energies among the fragmenting ions. Notwithstanding these difficulties, it was observed that many even-electron hydrocarbon cations derived from a wide range of precursor molecules had closely similar metastable-peak abundance ratios, showing the ease with which isomeric hydrocarbon cations can rearrange prior to their metastable fragmentation. Good examples are the C_6H_{10} isomers, 30 of which have been examined; they all, irrespective of their initial structure, produce the cyclopentenyl, C_5H_7^+ , cation when their molecular ions lose a $\text{CH}_3^\bullet$ radical. The metastable ion behaviours of the C_5H_7^+ fragment ions are identical.

A more stringent test for ion structure comes from the examination of energy-resolved metastable peaks. **Figure 6** shows the signals for loss of a hydrogen atom from the isomeric $\text{C}_2\text{H}_4\text{O}^{+\bullet}$ ions, $\text{CH}_3\text{CHO}^{+\bullet}$, $\text{cyc-CH}_2\text{OCH}_2^{+\bullet}$ and $\text{CH}_2\text{CHOH}^{+\bullet}$. The shapes are clearly structure-characteristic and so could, for example, serve as identifiers for $\text{C}_2\text{H}_4\text{O}^{+\bullet}$ m/z 44 fragment ions

Figure 6 The energy-resolved metastable peaks for the loss of H^+ from three isomeric $\text{C}_2\text{H}_4\text{O}^{++}$ ions. Note that the peak widths do not have a common scale. The half-height widths for the three signals are 35, 11 and 41 V from left to right.

generated from different precursor molecules. Thus, for example, it has been shown that ionized 2-propanol, $\text{CH}_3\text{CH}(\text{OH})\text{CH}_3^{++}$, loses CH_4 by two competing eliminations, one yielding $\text{CH}_3\text{CHO}^{++}$, and the other $\text{CH}_2\text{CHOH}^{++}$. The metastable peak for H loss from m/z 44 being composed of the two right-hand signals in **Figure 6**, the narrow component sitting atop the broad.

It is worth noting, however, that the above observations are phenomena that only allow the above $\text{C}_2\text{H}_4\text{O}^{++}$ ions to be distinguished. The details of the physical chemistry of the H-loss processes are known and, for example, the structure from which $\text{CH}_2\text{CHOH}^{++}$ ions actually lose their H atom is the (uncommon) $\text{C}_2\text{H}_4\text{O}^{++}$ isomer, the carbene ion CH_3^+COH .

Isotopic Labelling and Metastable Peaks

In studying ion fragmentation mechanisms, particularly molecular eliminations, it is important to discover which atoms are lost in the process. The use of isotopic labels to solve such problems is a long-established practice in organic chemistry. In general, the effect of label atoms on a normal EI mass spectrum does not provide definitive evidence for a reaction mechanism; this results from the possible multiple origins of fragment ions, especially those of lower m/z ratio. However, as described above, a metastable peak exactly defines an ion dissociation pathway and so here isotopic labelling has great utility. In particular, if MIKE mass spectra are examined, the incorporation of label in the sample molecule need not be

complete; mass selection allows the isolation of an ion containing the desired isotope(s). This is useful when, for example, H,D exchange is performed in the mass spectrometer inlet system using D_2O to exchange hydroxyl, amino or even α -to-keto hydrogen atoms.

An important result of labelling experiments on metastable ions was the demonstration that in many species, especially hydrocarbon cations, complete loss of the positional identity of H and C atoms preceded fragmentation. This, of course, obscures all reaction pathways and so structures of fragmenting ions and their products have to be determined by other routes. Such statistical loss of labelled atoms is referred to as 'atom scrambling'. The butyl cations, C_4H_9^+ , can serve as an example. $\text{CD}_3(\text{CH}_3)_2\text{C}^+$ loses methane as CD_3H , CD_2H_2 , CDH_3 and CH_4 in the statistical random ratio of $6!/5!$ to $3!6!/2!4!2!$ to $3!6!/2!3!3!$ to $6!/4!2!$ or 2:15:20:5 and $(\text{CH}_3)_3^{13}\text{C}^+$ loses $^{13}\text{CH}_4$ to $^{12}\text{CH}_4$ in the ratio of 1:3. All C_4H_9^+ isomers behave similarly, showing that at energies below the dissociation limit for CH_4 loss, many isomeric structures are accessed. Isotopic labelling and metastable ion studies can also reveal unexpected mechanisms, hidden in the normal mass spectrum. Two examples should suffice. The mass spectrum of benzoic acid, $\text{C}_6\text{H}_5\text{COOH}$, is very simple with the only major fragments corresponding to simple bond cleavages; e.g. $\text{C}_6\text{H}_5\text{COOH}^{++}$, $\text{C}_6\text{H}_5^+\text{CO}$ and C_6H_5^+ , are the dominant signals. Metastable $\text{C}_6\text{H}_5\text{COOH}^{++}$ ions lose OH^+ as expected, but astonishingly, metastable $\text{C}_6\text{H}_5\text{COOD}^{++}$ ions lose OD^+ and OH^+ , in the ratio of 1:2. That a hidden exchange between carboxyl and the two *ortho* H atoms has taken place was shown by metastable *ortho*-dideuterio

benzoic acid ions losing $\text{OD}^\bullet$ and $\text{OH}^\bullet$ in exactly the inverse ratio.

The unexpected complexity of ion rearrangement processes is also well exemplified by the metastable loss of HCN from ionized benzonitrile $\text{C}_6\text{H}_5\text{CN}^{*\dagger}$. Here, only some 5–7% of the nitrile carbon is present in the HCN eliminated. The participation of linear isomers of the aromatic nitrile ion has been demonstrated.

Neutral Species Lost in Metastable Ion Fragmentations

When metastable ions fragment, a neutral radical or molecule is generated. In most circumstances the identity of this neutral is not problematic and for example, is commonly a small molecule, H_2O , CH_4 , CO , C_2H_4 or free radical $\text{CH}_3^\bullet$, $\text{OH}^\bullet$, $\text{C}_2\text{H}_5^\bullet$, $\text{HC}^\bullet\text{O}$, etc. The distinction between isobaric species (e.g. CO , C_2H_4 , $\text{C}_2\text{H}_5^\bullet$, $\text{HC}^\bullet\text{O}$) may be made by the simple experiment described below.

If an ion-beam deflector electrode is placed in front of the collision cell in the second field-free region of a sector mass spectrometer (see **Figure 1**), then all mass-selected ions and their charged fragments may be deflected from the beam path, and only the neutral products from ion fragmentation will enter the collision cell. Neutral fragments having kV translational energies are readily ionized by collision with a target gas (e.g. He or O_2), producing the characteristic mass spectrum of the neutral species.

This technique has, for example, shown that HNC rather than HCN is lost from metastable aniline

molecular ions and that ionized methyl acetate loses $^\bullet\text{CH}_2\text{OH}$ radicals rather than $^\bullet\text{OCH}_3$ as the lowest-energy fragmentation route.

Microwave spectroscopy covers, typically, the frequency range from 1–2 GHz to several THz. In this spectral region the rotational spectra of molecules which possess a permanent (or induced) dipole moment can be observed. The analysis of these spectra gives information on the geometrical structure of the molecule and the centrifugal distortion effects. Other information such as dipole moment, quadrupole coupling constants, spin rotation constants, etc. can also be determined. In the case of molecules that present large amplitude motions, like the internal rotation of a methyl group or ring deformation for cyclic compounds, the potential barrier is also accessible from the observation of line splittings. The large selectivity of microwave spectroscopy allows the identification of compounds of interstellar medium, planetary atmospheres and minor components of the earth's atmosphere.

The number of molecules which have been studied by this method is increasing every year. Their complexity ranges from diatomic molecules to moderate size molecules (up to 30 atoms). Unstable species such as molecular ions, radicals, reactive molecules, molecular complexes, etc. can also be studied. The resulting molecular constants are regularly the subject of extensive compilations.

Spectrum Measurements

Microwave spectroscopy uses tunable coherent sources of radiation such as microwave synthesizers, solid state oscillators (Gunn diodes) or electronic tubes (klystrons). These oscillators can be operated in their fundamental mode (up to 120 GHz) but harmonic generation is commonly realized with frequency multipliers up to 500 GHz, and has been used to reach 1 THz on occasions. Backward wave oscillators are available up to 1.2 THz in

their fundamental mode. **Figures 1 and 2** show typical rotational spectra recorded with these types of sources. Different techniques can be used to work in the THz region:

- far-infrared laser tunable sideband generation,
- mixing of two infrared radiations (CO₂ lasers) and a microwave tunable radiation,
- photomixing of two diode lasers,
- far-infrared Fourier transform spectroscopy.

The detectors are generally Schottky diodes or InSb helium-cooled bolometers in the millimetre and sub-millimetre wave region.

Stark modulation has been widely used at microwave frequencies, while source modulation is the most common technique for millimetre and submillimetre spectroscopy. A new technique, microwave Fourier transform spectroscopy, has been developed to obtain increased frequency resolution and sensitivity. A macroscopic polarization is created in the sample by a microwave pulse of appropriate strength and duration. The sample emits then a signal which decreases in time owing to relaxation effects. The Fourier spectrum of this decay signal contains the frequencies corresponding to rotational transitions of the sample. This technique is available between 1 and 40 GHz.

The sample is prepared in the gas phase, at low pressures (typically 10–30 mTorr) for stable or not too unstable species. Reactive species are prepared inside a free space cell, usually made of a pyrex glass tube, by different techniques: microwave discharge, a.c. or d.c. glow discharge, thermal decomposition or reaction, photochemical decomposition. This last process needs high power excimer or CO₂ lasers, but is much cleaner than electrical discharges. **Figure 3** shows spectral lines of linear C₃H, produced in a glow discharge of C₂H₂, CO and H₂ in a cell cooled to liquid nitrogen temperature to obtain stronger signals. Molecular ions can also be observed within electrical discharges: the sensitivity of the spectrometer is then increased by using the velocity modulation technique. This technique is based on the Doppler shift of ion spectra caused by the discharge electric field. An additive magnetic field usually produces an enhancement of the spectrum. For van der Waals or hydrogen-bonded complexes a supersonic expansion is generally needed. The monomers are diluted (several %)

in rare gases (usually argon). The collisionless regime in molecular beams prevents the rapid destruction of the molecular complexes. **Figure 4** represents part of the spectrum of the phenol–water complex.

The isotopic species can be studied in natural abundance for ^{13}C , ^{15}N and most of the elements. In the case

of deuterated isotopomers an enriched sample is generally needed. The line frequency measurements are made with a very high accuracy: 1 kHz for microwave Fourier transform measurements between 2 and 20 GHz to 50–300 kHz for far-infrared measurements up to 2–3 THz. The line shape is usually a Doppler or a Voigt profile if the collisional broadening becomes important. The Doppler half-maximum halfwidth is given by $\Delta\nu_D$ (MHz) = $3.581 \times 10^{-7} (T/m)^{1/2} \nu_0$, where T is the temperature in K, m the molecular weight in atomic mass units, ν_0 the frequency of the transition in MHz. For example, the $J=3-2$ transition of CO at 345.8 GHz has a Doppler width of 400 kHz.

The collisional broadening increases linearly with pressure: $\Delta\nu_L = \gamma_L P$, where $\Delta\nu_L$ is the collisional half-maximum halfwidth. Typical values for collisional broadening parameters γ_L are 1–10 MHz Torr $^{-1}$, as shown in **Figure 5**; the value of γ_L generally increases when the temperature decreases. At low pressures the line broadening is mostly due to the Doppler effect and is the general cause which limits the resolution of the spectrometer. The resolution can be increased by using sub-Doppler techniques such as saturated absorption spectroscopy (or Lamb dip spectroscopy) or by generating a microwave radiation perpendicular to the motions of the molecules when using a molecular beam.

Most often, molecules are studied in their ground electronic and vibrational state but rotational spectra in

Figure 3 Typical traces of the spectral lines for the ν_4 ($^2\Sigma_u^-$) state of C_3H (CCH bending mode). The centre frequencies of the doublet lines are given in the figure. The spin splitting becomes large as N increases. Reproduced with permission from Yamamoto S, Saito S, Suzuki H et al. (1990) Laboratory microwave spectroscopy of the linear C_3H and C_3D radicals and related astronomical observation. *Astrophysical Journal* 348: 363.

vibrationally excited states (up to $1000\text{--}1500\text{ cm}^{-1}$) are commonly observed. **Figure 6** shows a stick diagram, reproducing the relative intensities of the lines of the rotational spectrum of C_3S in the ground and various excited states: the vibrational energies for $\nu_5=1$ and $\nu_4=1$ are, respectively, 150 and 490 cm^{-1} . The observation of rotational spectra in excited electronic states is more difficult because of their short lifetime.

Rotational Constants and Geometrical Structure

Most of the spectra recorded in the microwave region are rotational spectra. Among the molecular parameters used for the modelling of these spectra the most important are rotational constants. These constants are related to the principal moments of inertia by the relation $A = b/(8\pi^2 I_a)$. For light molecules such as hydrides, the spectrum lies in the millimetre or submillimetre wave region: for HCl the $J=1\text{--}0$ transition, which is the lowest frequency transition, lies near 626 GHz . This is one of the reasons for the development of spectroscopy in the

Figure 4 A 172 MHz broad-band scan (lower trace) and high-resolution spectrum (upper trace) of phenol and water in helium at a stagnation pressure of 100 kPa . Three lines can be recognized in the low-resolution spectrum: a doublet consisting of a strong and a weak component of the $6_{06}\leftarrow 5_{05}$ transition of the phenol- H_2O complex and the low frequency component of the $2_{12}\leftarrow 2_{21}$ internal rotation doublet of the phenol monomer. In the high-resolution spectrum, the lines appear as Doppler doublets. Reproduced with permission from Gerhards M, Schmitt M, Kleinemans K, and Stahl W (1996) The structure of phenol-water obtained by microwave spectroscopy. *Journal of Chemical Physics* 104: 967.

terahertz domain. For heavy molecules the spectrum lies mostly in the microwave region. Nevertheless high J transitions are measured at millimetre and submillimetre wavelengths. This allows the analysis of the centrifugal distortion. The rotational Hamiltonian is generally expressed as a series expansion of the even powers of the angular momentum operator. The first term contains the rotational constants, and the following terms contain, respectively, the quartic, sextic, octic, etc. centrifugal distortion constants. The effects of these terms are important at high rotational excitation. This expansion is usually satisfactory except for floppy molecules, i.e. molecules which exhibit large amplitude motions (H_2O , CH_3OH , etc.). Quartic and sextic centrifugal distortion constants are usually determined during the analysis of the spectrum on a broad frequency range. They can be related to the force field and be estimated from *ab initio* calculations. Some empirical correlations were also found between these constants and the rotational constants: this allows also an estimation which can be useful at the beginning of the identification of a new spectrum. **Figure 7** shows an example of correlation found between a sextic centrifugal distortion constant and the rotational constant B for a class of symmetric top molecules.

The rotational constants are a source of information on the geometrical structure of the molecule. By combining the rotational constants of a parent molecule

Figure 5 Nitrogen-broadened widths of the $J=8 \leftarrow 7$ lines of N_2O at $T=295\text{ K}$; pressure of N_2O : 30 m Torr.

(usually the main species) and isotopically substituted daughter molecules it is now possible to determine a complete experimental structure which lies very close to the equilibrium structure. These results mainly concern moderately sized molecules, containing between 3 and 8 atoms. A pure experimental equilibrium structure is difficult to obtain because the rotational constants in all fundamental vibrational states are needed to determine the equilibrium rotational constants. For the higher excited states the data are usually obtained from high resolution IR spectroscopy. In many cases a lot of interactions occur between these vibrational states (Fermi resonances, Coriolis interactions, etc.) which make it difficult to obtain unperturbed rotational constants.

Another type of problem which arises in structure determination is the ill-conditioning of the system of equations that link the moments of inertia and the structural parameters. To obtain reliable parameters we have to incorporate additional data obtained from other

techniques: electron diffraction, *ab initio* calculations, empirical relations, etc. Bond distances with an accuracy of $0.001\text{ \AA}$ and bond angles with an accuracy of 0.2° can then be determined.

For molecules that contain a greater number of atoms, different conformers are often present and generally observed: their spectra are rather well separated and the comparison between their intensities gives an order of magnitude of their relative energy difference.

Determination of Molecular Parameters

Rotational constants and centrifugal distortion constants are not the only parameters accessible by microwave spectroscopy. In the case of linear and symmetric tops, doubly degenerate vibrationally excited states (bending modes for examples) are present and their spectra are slightly more difficult to analyse. More parameters are

Figure 6 Spectral pattern and relative intensities of C_3S transition lines. Reproduced with permission from Tang J and Saito S (1995) Microwave spectrum of the C_3S molecule in the vibrationally excited states of bending modes ν_4 and ν_5 . *Journal of Molecular Spectroscopy* 169: 92.

Figure 7 Plot of $\log |H_J|$ against the function of $\log B$ for various C_{3v} symmetric tops: B is the rotational constant, H_J is one sextic centrifugal distortion constant. needed: l-type doubling constants, rotation–vibration interactions constants, etc. It should be noted that for symmetric tops the axial rotational constant is not accessible by pure rotational spectroscopy. Its determination remains a difficult problem and needs the study of IR spectra (including hot bands and combination bands). Combined high-resolution microwave and IR studies have become the best way to determine a coherent set of

molecular parameters for linear and symmetric tops. Owing to the growth in high quality experimental data, theoretical developments on the rovibrational Hamiltonian of symmetric tops have been made. The equivalence between different reductions of this Hamiltonian has been checked experimentally.

Large amplitude motions produce specific features in rotational spectra. Internal rotation of one methyl group induces a splitting of most of the lines into two components. This splitting depends on the barrier height and the geometry of the molecule. For high barriers the splitting is usually small but easily resolved by microwave Fourier transform spectroscopy. The splittings are larger in the excited torsional states but a complete theoretical description of the spectra is difficult. A prototype molecule in this field is acetaldehyde CH_3CHO .

Cyclic molecules containing an heteroatom in the ring (O, S, etc.) also present large amplitude motions due to ring deformations, such as ring-puckering. The observation of rotational spectra in excited states is not a problem because these states are low in energy.

The behaviour of the rotational and centrifugal distortion constants with the vibrational quantum number can be related to the potential of the ring deformation (see **Figure 8**). Microwave measurements are then complementary to far-IR observations of the vibrational transitions (usually obtained at low resolution).

Hyperfine structure in rotational spectra is due to nuclei with a spin $I > \frac{1}{2}$ whose electric quadrupoles interact with the electric field gradient. The corresponding splittings depend on the nucleus involved in this interaction and its spin value. The spectra of numerous

Figure 8 Comparison of observed ($\square$) and calculated (—) variations of the quartic centrifugal distortion constant Δ_{JK} with the ring-puckering quantum number ν for methylene cyclobutane. molecules containing ^{35}Cl , ^{37}Cl , ^{79}Br , ^{81}Br , ^{127}I , ^{14}N , ^{17}O , ^{33}S have been studied and the corresponding quadrupole coupling constants determined. The deuterium coupling constants have been studied more recently because the splittings are smaller (several tens of kHz) and were observed only by very high resolving spectrometers (molecular beam maser, microwave Fourier transform spectrometers). These spectrometers also allow the more or less complete resolution of the hyperfine structure due to two or more nuclei. Spin rotation and spin-spin coupling constants are also accessible by measuring the transitions involving the lowest values of the rotational quantum numbers.

Dipole moments are determined by applying an external electric field (Stark effect). The accuracy of the experimental dipole moments is about 0.001 D under good conditions. It is mainly limited by the homogeneity of the electric field. The calibration is generally done by using the OCS dipole moment as a reference. The vibrational dependence of the dipole moment can also be studied. In some cases (allene for example) the molecules possess a vibrationally induced dipole moment and no permanent dipole moment in the ground state. In some spherical tops (CH_4 , SiH_4 , etc.) a very small dipole moment induced by centrifugal distortion has been measured ($\sim 10^{-5}$ D).

Atmospheric Applications

The atmospheric transmission between 0 and 1 THz, at the ground level, is dominated by the absorption lines of water vapour and, to a less extent, by some absorption lines due to molecular oxygen (magnetic dipolar

transitions), as shown in **Figure 9**. These strong, broad absorption lines are a limiting factor for the observations of other signals, i.e. absorptions due to minor components of terrestrial atmosphere or interstellar emissions. Nevertheless microwave sensors play an important role in atmospheric measurements either in ground-based facilities or in air- and spaceborne ones. The advantages of microwave sensors are the following:

- accurate measurements over the altitude range 0–100 km, mostly independent of clouds and aerosols,
- high frequency resolution and good sensitivity using superheterodyne receivers,
- accurate measurements of the ozone profile and trace constituents of importance in catalytic ozone destruction cycles (ClO etc.).

In any event the data collected have to be analysed together with data obtained in the UV, visible and IR parts of the electromagnetic spectrum for a reliable interpretation.

The frequency of the centre of the absorption line is not the only parameter which is necessary. The line shape is dominated by molecular collisions up to an altitude of 80 km. The collisional broadening parameters with N_2 and O_2 , and their temperature dependence, are determined in the laboratory: they are of a crucial importance for data interpretation. Experimental laboratory data with an accuracy of 2–3% are now obtained for the collisional broadening coefficients; the temperature dependence is usually determined with a greater uncertainty but this does not influence the data interpretation too much. These laboratory data are also useful benchmarks for theoretical calculations and model testing.

Millimetre-wave sensors represent the only ground-based technique for the observation of stratospheric ClO, the abundance of which is fully correlated to ozone depletion. Moreover this technique allows a continuous observation of ClO, and the analysis of its diurnal cycle, as shown in **Figure 10**. The most frequently observed line is the $J = \frac{15}{2} - \frac{13}{2}$ transition at 278.632 GHz, which is the most intense one. This line is also one of the less overlapped lines, (interferences with ozone lines located in the neighbourhood are not too strong). This line is also broadened by the hyperfine components. The total line shape contains the contributions of the successive atmospheric layers, and its interpretation leads to the vertical concentration profile of ClO.

Another application of microwave spectroscopy is the analysis of pollutants. Microwave Fourier transform spectrometers have been used to analyse polluted air samples, in the frequency range 10–26 GHz. The air sample is supersonically expanded in a Fabry–Perot resonator, the technique being the same as the one used for the study of molecular complexes. The difference is in the carrier gas which is now air instead of argon. Laboratory studies show that the sensitivity decreases by a

Figure 9 Atmospheric transmission in the submillimetre and far-IR from (top) a very good high-altitude ground-based site (Mauna Kea, Hawaii, at 4.2 km) and from (bottom) an airborne observatory (e.g. KAO at 12 km). factor of 30 when argon is replaced by air. Nevertheless, the sensitivity is still high enough to allow the detection of most of the polar constituents of the sample. Another advantage, already mentioned above, is the very high frequency resolution, which permits the unambiguous identification of a great number of pollutants.

Radioastronomy

One of the most fruitful application of laboratory microwave spectroscopy over the last 20 years is the analysis of the molecular content of interstellar clouds. These clouds contain gas (99% in mass) which has been mostly studied by radioastronomy, and dust, whose content has been analysed mostly by IR astronomy. The clouds rich in molecular content are dense or dark clouds (they present a large visual extinction), with a gas density of 10^3 – 10^6 molecules cm^{-3} , and temperatures of $T < 50$ K. At these low temperatures only the low-lying quantum states of molecules can be thermally (or collisionally) excited, i.e. rotational levels. Spontaneous emission from these excited states occurs at microwave wavelengths. In some warm regions of dense clouds (star formation cores) the absorption of IR radiation produces rotational emission in excited vibrational states. Other rich chemical sources are the molecular clouds surrounding evolved old stars, such as IRC +10216, and called circumstellar clouds.

In the 1980s and 1990s a lot of radiotelescopes were built, with large antennas (diameter = 10–30 m) and sensitive receivers in the millimetre and submillimetre range. More than 100 different molecular species were found in the interstellar medium (see **Table 1**) and, for some of them, various isotopic species were also detected. The identification of interstellar species is not easy because of the high density of lines in the spectra of some interstellar clouds. A millimetre wave spectrum of the Orion nebula is shown in **Figure 11**. This is owing to the richness of the chemistry in these clouds and also to the improved sensitivity of the latest generation of radiotelescopes. The characterization of the molecules present in these dense clouds requires a knowledge of the laboratory spectra. In some cases (C_3H_2 , HC_5N , etc.) the identification was first made in the interstellar medium, before laboratory evidence. Nevertheless in the case of HC_{11}N , the highest member of the cyanopolyne series, interstellar detection was claimed at the beginning of the

1980s. This molecule was subsequently produced in the laboratory and its rotational spectrum does not fit the interstellar line. A search for HC₁₁N with the new experimental data was at first unsuccessful but, finally, a deeper search confirmed the presence of HC₁₁N in the interstellar medium. A lot of laboratory studies have been devoted to this family of molecules: the rotational spectrum of HC₁₇N has been observed, and numerous hydrocarbons of the type C_{*n*}H_{*m*}, with $n > m$, have been produced in discharges and their spectra analysed.

The detection of isotopomers in interstellar medium is a source of information on the elemental isotopic ratio. Molecules containing the following atoms have been detected: D, ^{13}C , ^{15}N , ^{17}O , ^{18}O , ^{33}S , ^{34}S and ^{36}S . The deuterated species are of particular interest because their abundances bring useful information on the chemical processes which take place in the peculiar conditions of the interstellar medium (isotopic fractionation).

Table 1 Interstellar molecules[illegible]

Figure 11 Millimetre wave spectrum of the Orion nebula in the direction of the so-called Kleinmann–Low area. Rotational spectra from many molecules are seen; ν = frequency and T_A^* = antenna temperature, a measure of emission intensity. Reproduced with permission from Blake GA, Sutton EC, Masson CR, and Phillips TG (1987) Molecular abundances in OMC-1: The chemical composition of interstellar molecular clouds and the influence of massive star formation. *Astrophysical Journal* 315: 621.

Molecular hydrogen is the dominant molecule; the second most abundant molecule, CO, is four orders of magnitude less abundant. But H_2 has no strong transitions in the microwave regions; CO is mainly used to map interstellar clouds in our galaxy and others, and also in quasars. The observation of several lines of the same species gives information on the physical conditions in the interstellar cloud: temperature molecular density. In the case of the OH radical, the splitting of the observed microwave lines by the local magnetic field (Zeeman effect) is a way to evaluate its order of magnitude. Several molecular ions have been studied in the laboratory (H_2D^+ , H_3O^+ , CH_2D^+ , etc.) because

of their importance in interstellar chemistry, which consists mostly in gas phase ion–molecule reactions. But in many cases their reactivity prevents their interstellar detection. Radioastronomy has also been applied to the analysis of planetary atmospheres, together with infrared observations. Both CO and H_2O were detected in Mars and Venus, SO_2 in Io (a satellite of Jupiter), CO and HCN in Neptune. In Titan, a satellite of Saturn, HCN, HC_3N and CH_3CN were detected, indicating a complex photochemistry. More detailed mappings were undertaken more recently with interferometers working in the millimetre-wave region.

Figure 12 The $1_{10} \leftarrow 0_{00}$ HDO line at 465 GHz, observed at the Caltech Submillimetre Observatory, in comet Hyakutake. Two lines of methanol are present in the same spectrum. Reproduced with permission from Crovisier J and Bockelée-Morvan D (1997) Comets at the submillimetric wavelength in *ESA Symposium*, Grenoble, France.

Millimetre astronomy has also been found to be a powerful tool for the analytical chemistry of comets. This was fully demonstrated by the observations of two exceptional comets: Hyakutake (1996) and Hale-Bopp (1996–1997). The newly detected molecules in these two comets are: CS, NH_3 , HNC, HDO, CH_3CN , OCS, HNCO, HC_3N , SO, SO_2 , HCCS, HCOOH, NH_2CHO , CN, CO^+ , HCO^+ , H_3O^+ . This number is considerably bigger than the total number of molecules previously in comets. **Figure 12** shows the detection of HDO and methanol in the comet Hyakutake.

Increasing amounts of data are being obtained at higher frequencies, i.e. in the submillimetre region.

A survey of Orion was made between 607 and 725 GHz, and another one between 780 and 900 GHz has been started. These spectral regions are well suited for the detection of light hydrides. They are limited by the atmospheric windows. A continuous coverage will be available with satellite observatories, which are planned for the beginning of the third millennium.

Microwave radiation, defined roughly as electromagnetic radiation with a frequency in the range of 3000 to 300 000 MHz (wavelengths from 10 to 0.1 cm), finds extensive use in chemistry and physics chiefly for two spectroscopic applications. The first of these involves the study of certain magnetic materials, especially paramagnetic substances, and is generally known as electron spin resonance spectroscopy. The second involves the spectroscopic study of the rotational energy states of freely rotating molecules in the gas phase. This latter field of investigation, properly known as rotational spectroscopy but universally and synonymously identified as microwave spectroscopy, is the subject matter of this article. Any instrument used to detect, measure and record the discrete and characteristic absorption of microwave radiation by gaseous molecular samples is thus commonly known as a microwave spectrometer.

General Description

According to the well-known principles of quantum mechanics, the rotational energies of a rotating molecule, considered approximately as a rigid framework of atoms, are limited to certain discrete, quantized values E_i . Upon irradiation of a gaseous molecular sample by microwave

radiation, an absorption of radiation is possible only if the frequency ν of the radiation satisfies the Bohr frequency relation

$$\frac{E_2 - E_1}{h} = \nu$$

where E_1 and E_2 are the initial and final rotational energies and h is Planck's constant (6.626×10^{-34} J s). When a molecule in the quantum state 1 absorbs radiation and is excited to the quantum state 2 we say a spectral transition has occurred. The spectral transitions permitted by the Bohr relation are further limited by other quantum mechanical rules known as selection rules. The net result is that a particular molecule will exhibit typically tens, hundreds or even thousands of relatively sharp, discrete, rotational absorption *lines* in the microwave spectral region. For gas samples at pressures of less than approximately 100 m torr the frequency widths of the absorption lines are very narrow (typically 0.1–1 MHz) so the resolving power of a microwave spectrometer is very high.

Quantum mechanical and electromagnetic theory provide an additional extremely important restriction upon the occurrence of rotational transitions, namely, to a first and generally adequate approximation they can occur only for molecules having non-zero electric dipole moments. Thus, microwave spectra occur for the polar molecules of water, carbon monoxide and acetone but not for the non-polar molecules of methane, carbon dioxide and benzene. It is worth stressing also that rotational spectra are produced only by gaseous molecules, not by liquids or solids. While this seems at first a serious limitation it should be noted that it is possible to vaporize even very refractory materials at elevated temperatures. Thus, the microwave spectrum of gaseous sodium chloride (NaCl) molecules is perfectly well known.

On the other hand, microwave spectroscopy is generally not useful for heavy molecules, i.e. those with molecular weights in excess of a few hundred atomic mass units. The reasons for this will be discussed later, but the result is that microwave spectroscopy tends to be far less generally applicable than other spectroscopic techniques such as IR or NMR spectroscopy.

Some detailed applications and theoretical aspects will be described later, but it is worthwhile noting in this general discussion that microwave spectroscopy clearly distinguishes molecular isotopic composition. Thus the

microwave spectrum of carbonyl sulfide (OCS) exhibits distinct and easily identifiable spectral lines for various isotopomers such as $^{16}\text{O}^{12}\text{C}^{32}\text{S}$, $^{16}\text{O}^{13}\text{C}^{32}\text{S}$, $^{16}\text{O}^{12}\text{C}^{34}\text{S}$, $^{17}\text{O}^{12}\text{C}^{32}\text{S}$, and $^{18}\text{O}^{12}\text{C}^{32}\text{S}$ in natural abundance. This means that microwave spectra provide very specific information about the individual isotopomers rather than some molecule imagined to be composed of the elements with their average atomic masses or weights.

Experimental Considerations

Microwave spectroscopic experimentation blossomed at the conclusion of World War II because of the military developments in microwave technology, especially the development of practical microwave generators such as the klystron (vacuum tube) oscillator, and of microwave detectors such as the silicon point contact mixer diode. Later developments led to the backward wave oscillator (BWO) and still more recent work in solid state electronics has led to the availability of a variety of entirely solid state microwave generators such as the Gunn diode. In accord with Maxwell's equations of electromagnetism, the wavelength of microwave radiation is perfectly adaptable for transmission in conducting metal tubing known as a waveguide or (depending upon the frequency) in specially designed coaxial cables. Microwave devices for attenuation, power splitting, impedance matching, frequency measurement and directional coupling are available. The Further reading section should be consulted for details of these and other rather specialized microwave components.

Figure 1 presents a block diagram of a typical continuous wave (CW) microwave spectrometer. The gas sample is contained typically in a one to three metre length of standard rectangular waveguide fitted at each end with vacuum-tight windows that are transparent to the

microwave radiation. The microwave generator is a klystron, BWO or solid state device, and has provision as shown for electronic apparatus for frequency stabilization and measurement. Modern microwave generators can have stabilities and accuracies as high as $1:10^7$ or $1:10^8$, which translates to 1 kHz or better. The microwave generator has provision through some electronic means for scanning the frequency over some appropriate range at selectable speeds. After passing through the sample cell, the microwave radiation is detected and further processed by a system of signal amplifiers. A critical aspect for obtaining high sensitivity is the use of square-wave electric field-modulation. This modulation, typically at a frequency of 5–100 kHz, is applied to a central electrode insulated from, and running the length of, the cell walls. The square-wave electric field, through the phenomenon of the Stark effect (see below), modulates the absorption signal at the square-wave frequency, thus permitting narrow band amplification and lock-in detection. Finally the resulting spectrum may be observed on an oscilloscope synchronized with the sweep speed of the microwave generator. Most modern instruments are computer interfaced, allowing powerful spectral manipulations and analyses. In this case the computer normally handles other tasks such as frequency range and sweep speed selection and control.

There are numerous variations to the basic design. In particular, the common rectangular waveguide gas-cell is often replaced with other structures for specialized experiments. For example, microwaves can be propagated through free space utilizing special microwave horns or antennae, so the metal surfaces can be largely eliminated for the study of reactive molecules. In this free-space design, the waveguide cell is thus replaced with a relatively large volume glass cylindrical enclosure fitted at its ends with transmitting and receiving horns. In still another design the microwaves are resonantly enclosed in a cavity whose physical size satisfies the boundary conditions for an electromagnetic standing wave according to Maxwell's equations. A particularly useful design for experiments requiring continuous high-speed pumping of unstable molecules is the microwave Fabry–Perot cavity. This design consists of two appropriately designed metal reflectors, typically circular discs with spherically machined reflecting surfaces. Microwave radiation is coupled into and out of the Fabry–Perot with appropriately designed coupling irises and the entire cavity is then enclosed in a large vacuum chamber attached to a high-speed pumping system. The unstable gas molecules of interest are produced by some means external to the cavity and are then rapidly injected into and pumped out of the cavity continuously.

The CW microwave spectrometer just described is a typical *frequency-domain* instrument. In the late 1970s it was demonstrated that *pulsed time-domain* microwave spectroscopy could be practically performed in analogy to the techniques already well known in other fields such as

Figure 1 Block diagram of a conventional Stark-modulated microwave spectrometer.

NMR spectroscopy. **Figure 2** depicts a block diagram of a modern version of a pulsed Fourier-transform microwave spectrometer. The particular instrument shown utilizes a Fabry-Perot cavity and a pulsed-gas nozzle, and is especially useful for detecting microwave spectra of molecular clusters in an expanding supersonic free-jet.

Ignoring some of the details, which can be obtained from the Further reading section, the basic idea of the instrument is that a short pulse of monochromatic microwave radiation (approximately 1 μ s in length) irradiates the gas sample in the cavity. If an appropriate transition exists within the bandwidth of the cavity (typically a few MHz), the radiation pulse produces a non-equilibrium ensemble of excited molecules which

then immediately begin emitting radiation as they return to equilibrium after the pulse has dissipated. The resulting microwave emission is processed by a succession of coherent mixing processes which eventually yields a low-frequency signal for computer processing. Normally the experiment is repeated hundreds or thousands of times (at typically a 10 Hz repetition rate) to accumulate an observable signal. In accord with the theory of the coherent emission, Fourier transformation of the signal is found to produce the ordinary absorption spectral line. To scan a complete spectrum it is necessary to move the cavity resonance and microwave frequency along in small overlapping steps, repeating the entire signal accumulation process at each frequency.

The result is that the FT-microwave spectrometer (FTMWS) produces the 'same' spectrum as the CW-spectrometer in a much more complex fashion. What are its advantages? As with all spectroscopic experiments carried out in the time domain, the data collection is inherently more efficient, so that the ultimate sensitivity of the FT-spectrometer is substantially higher (perhaps by a factor of 10–100 in practice). In addition, the FT instrument yields much narrower line widths than achievable in typical CW experiments, so the spectral resolution is even higher than for ordinary CW experiments.

Theoretical Aspects of Rotational Spectra

The rotational quantum states of molecules are characterized by quantum numbers which specify the angular momentum of the rotating molecules. For all molecules, regardless of geometry, the quantum number J , with values, 0, 1, 2, ..., specifies the total rotational angular momentum of the allowed energy states. (Note: we exclude from our discussion molecules having spin angular momentum, in which case a more careful specification of quantum numbers is necessary.) For all linear molecules this quantum number suffices to describe the rotation energy levels (aside from some special effects arising from vibrational motions) in the absence of additional applied fields. The permitted spectral transitions are limited by the selection rule $\Delta J = \pm 1$, i.e. transitions can occur only with a change of one unit of angular momentum. Thus, a typical observed microwave transition for $^{19}\text{F}^{12}\text{C}^{12}\text{CH}$ (in conventional notation) is the $J=2 \leftarrow 1$, occurring at $\nu = 38824.64$ MHz. The notation means the molecule is excited from the lower $J=1$ state to the higher $J=2$ state. For the linear molecule, the rotational energy states in the simplest approximation are given by the expression

$$E = bBJ(J+1)$$

where $B = h/8\pi^2 I$ and I is the classical moment of inertia of the molecule. The term B is known as the 'rotational constant'.

For non-linear molecules, additional quantum numbers (or labels) are necessary, and moments of inertia must be defined for three axes, conventionally labelled a , b , c . Molecules such as CH_3Cl or NH_3 can be shown to have $I_a < I_b = I_c$ and are known as prolate symmetric rotors. By convention the a -axis is chosen to lie along the molecular threefold (or higher) axis of symmetry. Then the theory for the rotating symmetric rotor shows that the energies depend now not only upon J but also upon the quantum number K which specifies the component of total angular momentum J lying along the a -axis. The value of K is limited to $-J, -J+1, \dots, 0, \dots, J-1, J$. The

energy levels are then (to the first approximation again) expressed by

$$E = bBJ(J+1) + b(A-B)K^2$$

with definitions of the rotational constants as before, i.e. $B = h/8\pi^2 I_b$ and $A = h/8\pi^2 I_a$. The spectrum of the symmetric rotor is now determined by the selection rules $\Delta J = 0, \pm 1$ and $\Delta K = 0$. Note that the $\Delta K = 0$ rule leads to the result that the spectrum does not depend upon A at all. Moreover, $\Delta J = 0$, which is a formal rule according to theory, leads to no observable microwave transition. The net result is that the symmetric rotor microwave spectrum is essentially of the same structure as that of the linear molecule.

Non-linear or general polyatomic molecules (known as asymmetric rotors) with no threefold or higher axes of symmetry will generally have $I_a \neq I_b \neq I_c$. The rotational energy levels for this case have a complex pattern, depending upon the rotational constants A , B and C , the rotational angular momentum quantum number J , and two other pseudo-quantum numbers or labels related to K for the symmetric rotor. The spectrum is specified by the rules $\Delta J = 0, \pm 1$ again, and some additional symmetry rules involving the pseudo-quantum numbers and the dipole moment components μ_a , μ_b and μ_c . Some typical observed transitions for bicyclobutane (C_4H_6) are the $J=1_{1,0} \leftarrow 0_{0,0}$ at $\nu = 26625.55$ MHz and the $J=2_{2,1} \leftarrow 2_{1,1}$ at $\nu = 23995.38$ MHz. The transitions with $\Delta J = +1$ are known as R-branch lines while the $\Delta J = 0$ transitions are known as Q-branch lines.

The previous description has been based upon the so-called rigid-rotor approximation. In fact, molecules deform as they rotate, leading to the phenomenon known as centrifugal distortion. This produces small corrections to the previously described energy expressions, usually amounting to changes of less than 0.1%. Because of the very high precision of microwave measurements, such changes are, however, easily detectable and can be accounted for by appropriate theory. A number of other factors contribute to the finer details of microwave spectra. Some of these will be described in the next section and additional information can be obtained by consulting the Further reading section.

In addition to understanding the frequency axis (x -axis) of microwave spectra, it is important to have some knowledge about the intensity (or y -) axis. The theory describing the absorption of microwave radiation is complex, but it is worthwhile looking at some of the key factors. In a useful approximate theory for an asymmetric rotor, the intensity (a quantity proportional to the fraction of absorbed radiation) is given for a microwave transition by

$$\text{Intensity} \propto \sqrt{ABC} \mu_g^2 \nu^2$$

where the rotational constants have been defined previously, μ_g is the dipole moment along one of the axes $g=a, b, c$, and ν is the frequency of the transition. The expression leads to several key conclusions:

- (1) Microwave intensities vanish (i.e. no radiation is absorbed) if $\mu_g=0$, that is if the molecule is non-polar as mentioned earlier. Conversely, the squared dependence of μ strongly favours very polar molecules. Thus, all other factors being equal, the spectral intensities of nitriles (such as C_2H_5CN) with μ values of typically 4 debye will be approximately $(4/0.08)^2$, i.e. 2500, times greater than those of simple alkanes such as propane ($\mu \approx 0.085$ debye).
- (2) Intensities are generally greater at high frequencies, according to the ν^2 dependence. Heavy molecules, with large moments of inertia and corresponding small rotational constants exhibit their transitions generally at low frequencies while the converse is true for light molecules. Thus heavy molecules tend to have 'weak' spectra while light molecules have 'strong' spectra.
- (3) The factor $\sqrt{ABC}$ can be seen to emphasize the dependence upon molecular size and mass, or more precisely, upon moments of inertia. Small, light molecules are favoured because of their large rotational constants, while large, heavy molecules are discriminated against.

Applications of Microwave Spectroscopy

Structure Determination

Microwave spectroscopy is the premier physical method for determining accurate and precise molecular structures, i.e. values of interatomic distances (bond distances) and angles (bond angles). This capability arises because the moments of inertia are directly related to the coordinates of the atoms as follows:

$$I_a = \sum_i m_i (b_i^2 + c_i^2)$$

with similar expressions for I_b and I_c . In this expression, m_i is the mass of the i th atom while b_i and c_i are the b - and c -axis coordinates of the atom. Assignment, measurement and analysis of microwave spectra yield precise values of rotational constants A, B and C and hence values of I_a, I_b and I_c . Thus the latter quantities provide equations which permit the evaluation of atomic coordinates, a_i, b_i and c_i . Once the coordinates are known, distances and angles are also known. Thus, the bond distance between atoms i and j is given by

$$R_{ij} = \sqrt{(a_i - a_j)^2 + (b_i - b_j)^2 + (c_i - c_j)^2}$$

A number of problems dealing with molecular non-rigidity must be considered if accurate and meaningful bond distances are to be obtained. Ideally, one would like to determine the coordinates (and hence structure) for the hypothetical vibrationless molecule. Methods for achieving this ideal (to various approximations) have been developed, so that numerous accurate structures have been determined from microwave spectral data. The Further reading section provides examples of such molecular structure determinations.

Molecular Electric Dipole Moments

It has been mentioned that microwave intensities are determined by the size of the electric dipole moment, so one might suppose that accurate measurements of intensities might provide values of μ . This turns out not to be practical for various reasons. However, another very accurate procedure can be used. If an electric field is applied to a rotating molecule, a well-understood phenomenon known as the Stark effect splits the rotational transitions into a number of components. Precise measurements of these small splittings (typically several MHz) lead to very precise values of the electric dipole moment. Values of μ determined by this method refer to particular quantum states and are thus much more meaningful theoretically than those determined by classical bulk-gas relative permittivity (dielectric constant) measurements.

Hyperfine Structure

Molecules containing nuclei whose nuclear spin values satisfy $I \geq 1$ exhibit splittings of the rotational transitions known as hyperfine structure. The predominant cause of these splittings (which for most common quadrupolar nuclei is typically several MHz or less) is the nuclear electric quadrupole interaction. Measurements of the splittings and application of appropriate theory lead to values of a quantity known as the quadrupole coupling constant, usually symbolized as eQq . In this expression Q is the nuclear quadrupole moment (a fundamental nuclear constant), e is the charge on the electron, and q is the electric field gradient at the nucleus produced by the surrounding electron and nuclear charges. Coupling constants have been extensively measured for nuclei such as ^{35}Cl ($I=\frac{3}{2}$), ^{14}N ($I=1$) and D ($I=1$) in a variety of molecules. The resulting values provide important information about the chemical bonding of the atom in question. Note that several very common nuclei, such as ^1H , ^{12}C and ^{16}O , have $I=\frac{1}{2}$, 0 and 0 respectively and consequently produce no quadrupolar hyperfine splittings.

Internal Rotation

Molecules such as propane, methanol or acetone have methyl groups which undergo large amplitude torsional oscillations or internal rotation. This internal rotation is hindered in general by a potential barrier, and the well-known quantum mechanical theory for the effect often leads to observable splittings (typically a doubling) of microwave spectral lines. In general, for high barriers ($>1000\text{ cm}^{-1}$) the splittings are small (typically several MHz or less) while for low barriers ($\sim 300\text{ cm}^{-1}$ or less) the splittings can be very large (100 MHz or greater). Because of these easily observed splittings microwave spectral measurements have led to a wealth of data on molecular internal rotation barriers. Several related phenomena, involving the puckering or inversion of four- or five-membered ring compounds, or the inversion about pyramidal nitrogen (as for NH_3), have also been extensively studied by microwave methods.

Interstellar Microwave Spectra

One of the most exciting applications since the 1970s has been the observation of microwave (rotational) spectra of interstellar molecules. Common species such as formaldehyde, ammonia and methylamine and more exotic species such as HCO and $\text{H}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{CN}$ have been detected in various interstellar media. The experimental technique differs substantially from that outlined in **Figures 1** and **2**. In this case the interstellar molecular spectra are detected by collecting microwave emissions from interstellar space with large radio telescopes equipped with sensitive microwave receivers. An interesting feature of the interstellar spectra is that the spectral lines are generally Doppler-shifted from their laboratory 'rest' frequencies because the absorbing medium is moving rapidly relative to the background radiation source.

Multiple Irradiation Experiments

Microwave spectroscopy is often coupled with a second electromagnetic radiation field to perform specialized experiments. Thus microwave-optical double resonance (MODR) uses optical (say $400\text{--}800\text{ nm}$) radiation simultaneously. The optical radiation transfers molecules to excited electronic states which are then probed by the microwave radiation before the excited molecules return to the normal ground state. Similar experiments utilizing infrared radiation (IRMDR) permit probing of excited vibrational states. Analogous experiments using two microwave fields (MMDR) and a microwave and radio-frequency field (RFMDR) are very commonly used to produce spectral simplification and to aid in spectral interpretation. The double resonance experiments have

also been important for obtaining information about collisional energy transfer rates and mechanisms.

Studies of Weakly Bound Complexes

Since about 1980 there has been great interest in performing microwave studies of weakly bound species such as $(\text{H}_2\text{O})_2$, ArHCl and $(\text{HC}\equiv\text{CH})\text{HCl}$. These species are studied with the unique instrument shown earlier in **Figure 2**, known as a pulsed-nozzle Fourier-transform microwave spectrometer. The weakly bound species are formed by pulsing a gas-mixture through a small nozzle such that it undergoes a supersonic free-jet expansion. Complexes are formed rather abundantly in such expansions and are stabilized by the low temperatures ($<5\text{ K}$) achieved in the expansion. Pulsed FTMWS (synchronized with the pulsed nozzle) is then used to sensitively observe and study the rotational spectrum. Such investigations will surely continue to be of great future interest because they provide information on van der Waals and hydrogen-bonding forces, both of which are of critical importance to understanding intermolecular potentials.

Analytical Applications

The very high resolution and selectivity of microwave spectroscopy make it an excellent tool for qualitative analysis of gas-phase samples. Indeed, a substantial amount of effort has been placed by microwave spectroscopists in using the method to identify and characterize new chemical species, especially those which are unstable and hence difficult to study by more conventional techniques. Because microwave spectroscopy is readily adaptable to continuously flowing gas samples (with special cell designs as mentioned earlier) it is an ideal method for investigating the products of combustion, pyrolysis, photolysis or electric discharges. Examples of such studies include OH , CS , $\text{CH}_2=\text{NH}$, $\text{CF}_2=\text{C}=\text{C}=\text{O}$, HCO^+ , HNN^+ and many others. Of course, the last section described the unique application of microwave spectroscopy to unstable molecular clusters and earlier the high selectivity for isotopic analyses was mentioned.

The chief disadvantage of microwave spectroscopy for gas-phase analytical applications is that its sensitivity is not as high as for some other methods (such as laser fluorescence or mass spectrometry). For low molecular weight polar species such as SO_2 , NH_3 and NO_2 , analytical detection sensitivities using FTMWS instruments certainly extend into the parts per billion (ppb) range. However, as the molecular size and mass increase or the polarity decreases the sensitivities may fall more typically into the ppm range. Naturally, as with all spectroscopic methods, appropriate preconcentration or

preselection schemes may lead to effectively improved detection limits.

From the above it is clear that quantitative measurements at high sensitivities are most useful for a variety of small polar molecules which are of concern from the atmospheric environmental pollution point of view. Thus a substantial amount of effort has been and continues to be placed upon the development of field operable, portable microwave spectrometers for trace gas monitoring using both CW and FT instrumentation. Although there are likely to be continued applications of microwave spectroscopy to pure analysis problems in the future, it seems likely that the microwave spectrometer will continue to find its most exciting applications in the chemistry and physics research laboratory.

Introduction

A considerable variety of atmospheric pressure (AP) surface sampling and ionization techniques for use with mass spectrometry have emerged in recent years. The interest in these techniques has arisen because of the freedom and flexibility afforded when sample analysis is separated from the vacuum system of the mass spectrometer. Performing the sampling and ionization under ambient conditions enables materials to be examined *in situ* and even remote from the mass spectrometer. Many of these AP-surface sampling and ionization techniques require only minimal sample preparation and suffer few adverse matrix effects.

In all ambient ionization surface sampling techniques, ionization either occurs during surface sampling or as an ensuing process (secondary ionization). In this article, ambient surface sampling and ionization methods are classified first on the basis of the desorption process involved in each technique, and then subcategorized by the ionization method. This results in four primary categories: thermal desorption/ionization, laser desorption (ablation)/ionization, liquid and gas jet desorption/ionization, and liquid extraction surface sampling probe/ionization. **Table 1** summarizes these categories and lists the individual techniques that fall into each category.

Thermal Desorption/Ionization

In thermal desorption atmospheric pressure chemical ionization (TD/APCI) methods, heat is used to liberate the sample intact from the condensed phase to the vapor phase, either through the use of a heated gas passing over the sample, a resistively heated sample surface, or both. This approach is limited to relatively low-mass species

Table 1 Compilation of AP-surface sampling/ionization techniques

Surface sampling/ionization approach	Dominant surface sampling process		Dominant ionization process	Technique name	Acronym	Notes
	Mechanism	Driving force				
Thermal desorption/ionization	Thermal desorption	Heated gas flow, surface or combination	Liberation of organic salts from surface	Atmospheric pressure thermal desorption ionization	APTDI	Analysis of some organic salts is possible
			APCI – corona discharge	Thermal desorption/atmospheric pressure chemical ionization	TD/APCI	Commercially available; classic method for thermal desorption with a secondary ionization
				Atmospheric pressure solids analysis probe	ASAP	Commercially available; analyte is deposited on a glass capillary and inserted into the source
				Laser diode thermal desorption	LDTD	Commercially available; analyte is deposited in stainless-steel sample wells heated using IR laser
				Desorption atmospheric pressure chemical ionization	DAPCI	Generally used for detection of low mass and volatile analytes
Laser desorption (ablation)/ionization	Laser desorption (ablation)	Laser beam surface impact	APCI-like	Direct analysis in real time	DART	Commercially available; analysis from a wide range of surface types is possible
			APPI	Desorption atmospheric pressure photoionization	DAPPI	Choice of solvent vapor can dramatically affect ionization
			APCI-like	Plasma-assisted desorption/ionization	PADI	AC plasma
				Dielectric barrier discharge ionization	DBDI	AC plasma
				Atmospheric pressure glow discharge desorption ionization	APGDDI	DC plasma
			Secondary ionization by ICP	Laser ablation/inductively coupled plasma	LA/ICP	Commercially available; useful for elemental analysis of the sample
			Secondary ionization by APCI	Laser desorption/atmospheric pressure chemical ionization	LD/APCI	Used for analysis of proteins and peptides in gels
			Secondary ionization by ESI	Laser desorption/electrospray ionization	LD/ESI	
				Electrospray-assisted laser desorption/ionization	ELDI	Can form multiply charged ions from proteins
				Laser ablation with electrospray ionization	LAESI	Use of IR laser allows analysis of “wet” biological samples
				Infrared laser-assisted desorption electrospray ionization	IR LADESI	
				Matrix-assisted laser desorption electrospray ionization	MALDESI	
			Matrix-assisted ionization	Atmospheric pressure matrix-assisted laser desorption ionization	AP-MALDI	Commercially available; easily coupled with a variety of mass spectrometers

(~2000 Da or less) since thermally labile, highly polar, and high molecular-mass species are typically not amenable to vaporization by heating. Some ionic species can also be thermally desorbed, a process sometimes called atmospheric pressure thermal desorption ionization (APTDI). Once in the gas phase, the analyte molecules are typically ionized using APCI.

The basic TD/APCI approach originated in the mid-1970s. In the mid to late 1980s, commercial triple quadrupoles such as the Sciex Aromic 9100 cargo evaluation system and the British Aerospace/Sciex CONDOR Contraband Detection System became available. These units allowed for sample acquisition by direct vapor detection and/or collection of trace particle residue or

vapors, followed by TD and corona discharge APCI. A heated surface sampler and heated transfer line could be used to sample materials at distances up to 10 m from the mass spectrometer. These early systems provided analysts with the ability to rapidly analyze for targeted analytes in complex matrices without the need for either chromatography or a sample cleanup stage. Tandem mass spectrometry, specifically selected reaction monitoring (SRM), was used to provide selectivity in detection. The application area was typically the detection of drugs and explosive materials. Currently, at least one TD/APCI unit (the Scentinal, Mass Spec Analytical, Ltd.) is available commercially and can be used for detection of explosives, drugs, and other materials from boarding passes, gloves, and other surfaces.

Several TD/APCI sources reported since 2005 are now commercially available for use with a variety of mass spectrometers. These include the atmospheric pressure solids analysis probe (ASAP), laser diode thermal desorption (LDTD), and direct analysis in real time (DART). In ASAP, the simplest of these methods, a glass melting point capillary is inserted into a heated gas stream (100–500°C) emerging from the heated nebulizer (Figure 1). Analyte deposited on the capillary is thermally desorbed by the hot gas, ionized by APCI, and analyzed by mass spectrometry. The technique has proved suitable for the types of compounds typically amenable to ionization by APCI, including lipids, capsaicins, carotenoids from fresh biological samples, polymer additives, fatty acids, and drugs such as cocaine and acetylsalicylic acid.

LDTD uses an IR laser to thermally desorb samples that have been deposited onto stainless-steel sample wells in a 96-well plate specifically designed for the purpose (Figure 2). Heated air carries the thermally desorbed species through a transfer tube to the inlet of the mass spectrometer, where they are ionized by a corona discharge source. Carrier gas flow, laser power, and laser pulse duration must be optimized for optimal performance of this technique. LDTD-APCI has been used for high-throughput analyses of drugs, explosives, and antibacterial compounds.

In DART, shown in **Figure 3**, He gas flowing through a probe is subjected to a discharge at a needle electrode, producing ions, electrons, and metastable He atoms ($\text{He}^* (2^3\text{S}_1)$). Ions are removed from the gas stream, while the metastable He species are carried through a heated chamber, passing through a grid electrode before entering the ambient atmosphere. The grid electrode both acts as a source of electrons and serves to prevent ion-ion and ion-electron recombination reactions. The gas exiting the DART probe is directed at the surface to be analyzed, which is placed close to the inlet of the mass spectrometer. The ionization process in DART is similar to that in APCI; however, the reagent ion population originates from the gas-phase reactions of He^* produced in the discharge. In ambient air, which contains traces of water vapor, protonated water clusters become an important reagent and serve as a source of protons for desorbed analyte molecules. Electrons may undergo electron capture by O_2 , producing O_2^- , which reacts with desorbed analyte, forming negative ions. The distribution of reagent ions formed depends on the carrier gas, the ion polarity, and any dopants present in the gas stream. While sputtering or bombardment by ionized water clusters and metastable species has been proposed to contribute to analyte desorption in DART, desorption is also consistent with TD as a dominant process. While many species can be observed without substantial heating of the carrier gas, signal levels are significantly improved if the gas is heated to 200°C or more. DART has been used for the analysis of both polar and nonpolar compound classes from a variety of surface types, including thin-layer chromatography plates, glass surfaces, and whole bacterial cells, among others.

Desorption atmospheric pressure chemical ionization (DAPCI) can also be thought of as a simple TD/APCI system. In DAPCI, an emitter is aimed at the surface to be analyzed. The emitter can be composed of a capillary with a protruding, coaxially aligned, stainless-steel electrode with a sharp tip. An inert sheath gas, which can be heated, flows through the capillary at a high velocity. In some cases, a solvent vapor is introduced to the sheath gas. A high voltage ($\sim\pm 3\text{--}6\text{ kV}$) applied to the electrode induces a corona discharge at its tip, ionizing the introduced solvent vapor. Ionization mechanisms in DAPCI

are similar to those in other APCI ionization sources. Reagent ion species can be influenced by the polarity of the voltage applied to the electrode, and by the choice of sheath gas and solvent vapor. DAPCI desorption mechanisms are somewhat unclear, although TD is a dominant process when the sheath gas is heated. In other cases, the high-velocity sheath gas could conceivably carry particulates of material from the surface into the gas phase, where ionization can take place. However, desorption/ionization of analytes has been reported even without heat or high-velocity gas; for those cases, it has been proposed that static charge buildup on a dielectric sample surface facilitates ion desorption. DAPCI-MS has been used for desorption/ionization and detection of low-mass ions, including drug molecules, explosives, molecular markers for spoilage in meats, adulterants in food products, and agricultural chemicals. DAPCI-MS has also been used to differentiate between samples of tea obtained from various manufacturers.

Desorption atmospheric pressure photoionization (DAPPI) is similar in many respects to DAPCI, except that the reagent ion population is initiated by a photoionization process (**Figure 4**). In DAPPI, a heated solvent vapor jet is delivered to the sample surface via a microchip nebulizer. Ionization in the gas-phase results from ion-molecule reactions initiated using ultraviolet light. The ionization process is the same as that in atmospheric pressure photoionization (APPI) used with liquid introduction ion sources. As such, the choice of solvent (dopant) vapor may dramatically affect analyte ionization.

Plasma-assisted desorption/ionization techniques which appear to have a TD sampling component have also emerged in recent years. Two similar techniques are those referred to as plasma-assisted desorption/ionization (PADI) and dielectric barrier discharge ionization (DBDI). The desorption/ionization plasma in both experiments is typically created in a flowing stream of He by applying an alternating voltage between two electrodes, one of which is covered by a dielectric layer. The resulting non-equilibrium plasma consists of species like He^+ , ions, radicals, and electrons. The sample surface to be analyzed is placed in direct contact with the plasma jet created, resulting in analyte desorption and ionization.

Figure 4 Schematic view of the DAPPI setup. Reproduced from Haapala M, Pol J, Saarela V, et al. (2007) Desorption atmospheric pressure photoionization. *Analytical Chemistry* 79: 7867–7872, with permission from American Chemical Society.

Mass spectra obtained contain mainly molecular ionic species such as protonated analyte molecules and adduct ions; however, fragment ions are sometimes observed.

Neither the desorption nor the ionization processes involved in PADI and DBDI are well understood. It was thought that energy transfer from metastable He, ion impact, and radical-surface interactions could contribute to the desorption mechanisms. However, these processes would likely also result in modification of the analytes (such as radical addition reactions) on the surface or in the gas phase. In general, the mass spectra observed and the application space of these plasma-assisted desorption/ionization techniques are similar to TD with other APCI ionization methods. Plasma temperature is related to plasma power and thermal effects can become important.

Another TD sampling technique which can be used for surface sampling is atmospheric pressure glow discharge desorption ionization (APGDDI). This method, which can have a TD component from plasma heating of the sample surface, was first described in 1990 for TD of solid material from a probe, followed by ionization in the plasma. More recently, an AP glow discharge (constant current) source has been developed for surface sampling. The ability to interact a relatively small diameter (ca. 1 mm) plasma with a surface may provide desorption/ionization spatial resolution useful in spot sampling analyses and in chemical imaging.

Laser Desorption (Ablation)/Ionization

The basic laser desorption (ablation)/ionization source for surface sampling is relatively simple in concept. A pulsed laser beam is focused at a small target area on the surface to be analyzed, material is desorbed

(ablated)/ionized by the laser pulse, and the ions generated are analyzed by a suitable mass spectrometer. The mechanisms of the desorption and ionization processes are often complex and not always fully understood. In general, as the laser pulse is absorbed, the target area is excited and the analyte is desorbed, along with other species in the immediate vicinity. The desorbed material from the surface forms a reactive region just above the surface that can participate in proton and electron transfer, cationization, and radical reactions. The exact desorption/ionization pathways followed depend on the material properties of the compounds and on the laser irradiation parameters. A laser desorption (ablation) experiment typically generates many more neutral species than ions. Use of a distinct secondary ionization process following desorption (ablation) allows desorption (ablation) and ionization conditions to be independently optimized. This leads to increased overall ionization efficiency, provides flexibility in the types of ions created (e.g., atomic or molecular), reduces sample preparation requirements (e.g., no added chemical matrix), and opens up a variety of new applications. AP-LD/I can be divided into two subareas: AP laser desorption (ablation) with secondary ionization (AP-LD/SI) and AP-matrix-assisted laser desorption ionization (AP-MALDI).

Atmospheric Pressure Laser Desorption (Ablation) with Secondary Ionization

Laser ablation inductively coupled plasma (LA-ICP) is the oldest and most established of the AP-LD/SI type systems. LA-ICP systems have been commercially available for a number of years and are often configured for automated analysis that includes simple spot sampling as well as surface imaging (**Figure 5**). In a typical LA-ICP/MS experiment, the sample is placed in a closed ablation chamber that is flushed with argon or helium. The laser beam is focused on the sample surface through a window in the ablation chamber. With the appropriate laser conditions, material is ablated from the sample surface and carried in the argon gas stream to the ICP. The ICP is a separate excitation source in which the laser-generated particles are desolvated, vaporized, atomized, and ionized. The atomic ions created are then extracted by an atmosphere-to-vacuum interface and guided into the mass analyzer.

Because the ICP is an atomic ion source, LA-ICP/MS is confined to elemental analysis of the sample under study. However, major, minor, and trace element compositions can be measured and isotopic ratios determined. Sub-ng/g detection limits for laser spot sizes above 100 μm are obtained for many elements. The spot size examined can be reduced to just a few micrometers, but detection levels suffer when less material is sampled. LA-ICP/MS is an important tool in many scientific

Figure 5 Schematic of LA-ICP/MS setup. Reproduced from Günther D and Hattendorf B (2005) Solid sample analysis using laser ablation inductively coupled plasma mass spectrometry. *Trends in Analytical Chemistry* 24: 255–265, with permission from Elsevier.

fields, including geology, materials science, environmental science, forensics, archeology, and biology.

The use of LA-ICP/MS in biological studies is rapidly growing. LA-ICP/MS has been applied to the analysis of phosphoproteins and trace elements in proteins separated in gel electrophoresis and to map trace element distribution in thin tissue sections. Laser desorption (ablation) spot sizes with a lateral resolution in the sub-micrometer range have been achieved using the near field effect. This spatial sampling resolution is sufficient for spot sampling within and imaging of individual cells or organelles and could certainly find application in other fields as well.

Laser desorption atmospheric pressure chemical ionization (LD/APCI) is an AP-LD/SI technique using laser desorption for sampling and secondary ionization by an APCI process to produce molecular ionic forms of the sampled species (**Figure 6**). Secondary ionization by corona discharge APCI proves efficient at least in part because of the high number density of reagent ions in the region of the desorption plume. LD/APCI has been demonstrated for the direct analysis of proteins and peptides in polyacrylamide gels, and for the analysis of small biological molecules like amino acids, vitamins, and catecholamines. AP-LD/APCI has also been used for the detection of analytes separated on TLC plates.

An LA system can also be coupled with a flowing AP afterglow discharge source (a type of APCI) to form molecular ionic species from the ablated species on the surface. This technique has been demonstrated for analysis of drugs, for depth sampling of a pharmaceutical tablet, and for chemical imaging of caffeine-printed paper.

In the laser desorption electrospray ionization (LD/ESI) method, materials desorbed or ablated using a UV laser are ionized through reaction with the charged solvent droplets, protonated solvent species, or gas-phase ions

created using ESI. Another term for LD/ESI, sometimes seen in the literature, is electrospray-assisted laser desorption/ionization (ELDI). Using LD/ESI, it is possible to form multiply-charged species from macromolecular species such as proteins, to perform direct characterization of chemical compounds like amines on TLC plates, and to detect intact proteins in dried biological fluids (e.g., blood, tears, saliva, and serum), bacterial cultures, and tissue without the addition of a chemical matrix. Matrix-assisted laser desorption electrospray ionization (MALDESI) is very similar experimentally to LD/ESI, but uses a chemical matrix. Other LD/ESI techniques are laser ablation with electrospray ionization (LAESI), and infrared laser assisted desorption electrospray ionization (IR LADESI). These methods use an IR laser for desorption (ablation), which allows for the analysis of biological samples that have resonant frequencies in the IR because of their high water content.

Atmospheric Pressure Matrix-Assisted Laser Desorption Ionization

AP-MALDI was first reported in 2000, and is now commercially available. Commercial AP-MALDI sources can be coupled with ion trap mass spectrometers, orthogonal acceleration time-of-flight mass spectrometers, and hybrid instruments, taking advantage of their high duty cycle and the capability to perform MS/MS and MSⁿ (in the case of the ion trap) experiments. The newest commercial AP-MALDI sources are configured for fully automated sample analysis and chemical imaging of a surface. A schematic of a commercial AP-MALDI source is shown in **Figure 7**. The mechanism and efficiency of ion generation in AP-MALDI is believed to be the same as in vacuum MALDI. AP-MALDI mass spectra generally

Figure 6 Schematic representation of LD-APCI source. Reproduced from Coon JJ and Harrison WW (2002) Laser desorption-atmospheric pressure chemical ionization mass spectrometry for the analysis of peptides from aqueous solutions. *Analytical Chemistry* 74: 5600–5605, with permission from American Chemical Society.

contain less fragmentation than MALDI mass spectra, because of the rapid collisional cooling that occurs at AP, a process that benefits all the LD/I techniques. The most commonly used laser in AP-MALDI is the 337 nm UV nitrogen laser, although IR lasers can also be used. IR lasers are useful for sampling tissue *in situ*, the inherent water in samples like fruit or tissue acting as a matrix. Ion yields in IR-MALDI are lower than in UV-MALDI, although the secondary ionization processes discussed above can potentially provide a way to circumvent this limitation.

Liquid and Gas Jet Desorption/Ionization

Of the liquid and gas jet desorption/ionization techniques, desorption electrospray ionization (DESI) is probably the best known. In DESI, a pneumatically assisted electrospray ionization (ESI) source is mounted above the surface to be analyzed, and an external atmospheric sampling capillary fitted to the atmospheric sampling inlet of the mass spectrometer extends over and rests upon the region to be sampled (**Figure 8**). This arrangement allows for a larger surface area and a variety of sample geometries to be easily analyzed. Often the surface of interest is mounted upon a movable stage for aid in proper sample positioning, to improve the reproducibility of analysis, and to provide imaging capabilities. A voltage of ~ 4 kV is typically applied to the emitter. The high voltage, solvent flow, and co-axial nebulizing gas combine to create a high-velocity spray of charged solvent microdroplets. This spray is directed at the surface to be interrogated, creating an elliptical impact region where dissolution and desorption/ionization of the analyte take place.

The size of the DESI spray impact region and its point of impact relative to the sampling capillary are largely controlled by several parameters, including the distance of the DESI spray tip from the surface, its angle relative to the surface, and solvent and gas flow rates. A geometry-fixed DESI system which eliminates sample to sample parameter adjustment can be used for spot sampling. Any solvent appropriate for use in ESI can be used. Solvent additives typical for ESI (e.g., volatile acids and bases), as well as additives not usually used in ESI (e.g., nonvolatile salts like NaCl), or other chemical reagents can be used to enhance detection, a process often referred to as 'reactive DESI.' The spray/surface and analyte/surface interactions are also important parameters relating to the efficient desorption/ionization and sampling of analyte ions into the mass spectrometer.

In DESI, the charged solvent droplets impacting the surface dissolve some of the analyte and charged secondary droplets containing the analyte are subsequently liberated from the surface. Once an analyte is present in the charged droplets leaving the surface, the mechanisms giving rise to gas-phase ions from analytes in droplets during ESI are presumably in operation. Analyte ions and secondary charged droplets resulting from impact (which subsequently liberate analyte ions) are carried into the atmospheric sampling capillary of the mass spectrometer by the drag forces created by the vacuum system. The dominant desorption/ionization process in most DESI experiments has been referred to as 'droplet pick-up,' essentially a liquid-solid microextraction/liquid film-droplet sputtering process. Under typical operation conditions, the DESI spray impacts and wets a small elliptically shaped area on the surface.

Figure 7 Schematic of AP-MALDI setup. Reproduced from Doroshenko VM, Laiko VV, Taranenko NI, Berkout VD, and Lee HS (2002) Recent developments in atmospheric pressure MALDI mass spectrometry. *International Journal of Mass Spectrometry* 221: 39–58, with permission from Elsevier.

DESI-MS has the potential to become a powerful tool in a wide range of surface sampling applications. Some uses that may be especially valuable are the analysis of analytes on planar separation media, high-throughput sample analysis, and chemical imaging. There are indications that given the appropriate operating parameters, surface type, and analyte characteristics, one can achieve resolutions better than 100 μm with DESI-MS. Even with this modest spatial resolution, DESI has the potential to become a valuable analytical method for identifying the distribution of endogenous and even exogenous compounds in tissues.

DESI becomes desorption sonic spray ionization (DeSSI) when the variable high voltage is turned off and sufficient nebulizing gas velocity is provided. Sonic spray ionization (SSI) is a liquid solution introduction ionization source that uses only the forces of a high-velocity nebulizing gas to generate gas-phase ions from species in solution. Because no voltages are used, the spray plume is bipolar and nearly neutral, consisting of a distribution of positively and negatively charged droplets. This has the advantage of allowing the analysis of both positive and negative ions without the need to rapidly switch high voltages in the source. DeSSI has also been termed easy ambient sonic spray ionization (EASI). Species that are easily analyzed using ESI and DESI, such as preformed

Figure 8 Schematic rendering of a typical DESI-MS setup.

ions and very basic or acidic compounds, are also amenable to analysis using DeSSI, but less polar analytes may not be so easily detected.

Jet desorption ionization (JeDI) lies at the extreme of high liquid flow in these ‘spray’ desorption/ionization sources. In JeDI, a fused silica capillary is used to generate a highly collimated continuous liquid jet oriented in a position relative to the surface similar to the liquid droplet/gas jet emitter in DESI. A voltage of 4 kV is

Figure 9 Schematic of the automated Luftmann sealing surface sampling probe. Reproduced from Luftmann H, Aranda M, and Morlock, GE (2007) Automated interface for hyphenation of planar chromatography with mass spectrometry. *Rapid Communications in Mass Spectrometry* 21: 3772–3776, with permission from Elsevier.

applied at the emitter to the solution, which is pumped through the emitter at flow rates ranging 0.05 to 0.15 ml min^{-1} . The high-velocity jet stream produced in JeDI continuously erodes the sample surface and generates gas-phase ions. The ability to depth profile and spatial resolution as good as a few micrometers are some of the intriguing features of this technique.

Neutral desorption extractive electrospray ionization (NDEESI) retains the general desorption and sampling geometry of the DESI-type experiment, but the desorption step uses only a moderate velocity (ca. 10 ms^{-1}), room temperature gas jet. Ionization of desorbed material is accomplished by a secondary ESI process, although other ionization processes could also be used. This technique has been used to analyze small, volatile compounds, such as amines derived from spoiled meat and some less volatile explosives directly from skin. Species that are liberated from the surface as particles by the gas stream and transported to the ionization source might also be observed in the mass spectra.

Liquid Extraction Surface Sampling Probe/Ionization

In liquid extraction surface sampling, a confined liquid stream is brought to a surface through a probe acting as a liquid conduit. The analyte in contact with the liquid is

reconstituted or extracted from the surface and carried on to the ionization source. There are two basic types of surface sampling probes currently being used: a 'sealing' surface sampling probe (SSSP) and a 'liquid microjunction' surface sampling probe (LMJ-SSP). While the emphasis in each case has been on coupling with ESI, APCI has also been used, and there is no fundamental limitation to using other liquid introduction ionization sources. Once analyte is in solution and carried into the source, the analyte ionization is governed by the processes fundamental to the particular ionization source. Thus, these surface sampling probes can be applied to all species that can be dissolved, conducted into the probe, and ionized.

Sealing Surface Sampling Probe

Sealing surface sampling probes have been used exclusively for the analysis of relatively low molecular-mass compounds such as caffeine, other pharmaceuticals, or components of plant extracts separated on TLC plates. In the commercially available Luftmann-type sealing sampling probe and elution scheme, shown in **Figure 9**, the inlet capillary of a stainless-steel plunger that seals to the surface to be sampled is connected to an HPLC pump. The outlet capillary is connected to the ion source of the mass spectrometer. The zone of interest on the TLC plate is positioned under the probe and the surface sealed

Figure 10 Schematic illustration of the complete ES emitter/surface sampling probe ion trap mass spectrometer system. Blowup inserts show scale drawing of surface sampling detail and the details of the emitter/sampling probe solvent and gas flow paths. Monitors show images of a sampling probe at the array surface forming a liquid microjunction. Reproduced from Van Berkel GJ, Ford MJ, Doktycz MJ, and Kennel SJ (2006) Evaluation of a surface sampling probe electrospray mass spectrometry system for the analysis of surface deposited and affinity captured proteins. *Rapid Communications in Mass Spectrometry* 20: 1144–1152, with permission from Elsevier.

by compression with the cutting edges on the probe. By switching the valve from standby to extraction mode, the solvent that was previously flowing directly to the ion source travels to the surface, extracts the analyte from the surface, and then carries it into the ion source. Between elution steps, the probe is moved to a docking station, where the sampling face of the probe is automatically cleaned of accumulated particulate material from the surface by pressurized air.

Liquid Microjunction Surface Sampling Probe (LMJ-SSP)

In the LMJ-SSP, annular space between an inner and an outer capillary tube is used to deliver solvent to a surface. The inner tube is used to draw liquid from the surface to an electrospray or other source. This design is essentially a 'sipper' source that can be configured to sample

material at, in, or just above a surface. The LMJ-SSP sampling configuration is shown in **Figure 10**. To date, analytical applications of the LMJ-SSP for surface analysis have involved the sampling and analysis of drugs or proteins from wells on microtiter plates, drugs captured in solid-phase extraction cards, a variety of dyes, inks, or pharmaceuticals from paper or separated on hydrophobic reversed-phase (C8 and C18) thin-layer chromatography plates. The technique has also been demonstrated as a means to sample and detect exogenous compounds from thin tissue sections.

Conclusions

AP-surface sampling/ionization techniques for mass spectrometry and their associated acronyms have been emerging in the literature at a rapid rate over the last

several years. Many of these techniques are simply variations on an existing theme. In this article, we have sorted the array of techniques into four main sub-categories based primarily on the approach used for surface sampling (i.e., heat, photons, droplet or gas impact, and direct liquid extraction) that are further differentiated on the basis of the ionization process (e.g., APCI, ICP, and ESI). As other techniques are developed, it should be possible to place them within this classification scheme.

λ	photon wavelength

Ion imaging, as described here, is a multiplex detection technique used in gas-phase molecular reaction dynamics to visualize the breaking and formation of chemical bonds. The primary aim of the ion imaging technique is to reveal quantitatively the way in which energy associated with the processes that govern the breaking and formation of chemical bonds is released into the reaction products. The ion imaging technique is based on a combination of two more established techniques: optical spectroscopy (resonance-enhanced multiphoton ionization, REMPI) and two-dimensional time-of-flight mass spectrometry. Ion imaging measures the three-dimensional recoil (velocity, i.e. speed and angular distribution) of the ensuing fragments or reaction products in uni- and bimolecular reactions. Using resonance-enhanced multi-photon ionization, the recoil of individual quantum states (electronic, vibrational and/or rotational) of a selected fragment or reaction product can be measured. More extensive reviews covering various aspects of the ion imaging technique are available.

Principal Aspects

One of the major goals of molecular reaction dynamics, and of ion imaging, is to elucidate how the energy deposited into products of a molecular dissociation or bimolecular reaction is distributed over all available degrees of freedom. Consider a unimolecular dissociation initiated by absorption of a photon. Following dissociation, the nascent fragments will recoil into space, away from the point where the reaction was initiated. The speed of the products will depend on the amount of

energy deposited in the translational degrees of freedom, and on the masses of the products. The recoil of the fragments or reaction products does not have to be isotropic. In a laser-induced dissociation, the angular distribution of the photofragments depends on the polarization vector of the photolysis source, on the symmetry of the electronic states involved, and on the lifetime of the activated complex. In the case of a bimolecular reaction, the products will be scattered at various angles with respect to the centre-of-mass velocity vector. Measurement of such recoil will reveal directly whether reaction products are, for example, forward or backward scattered. Additionally, reaction products can be formed with excess internal energy distributed over the electronic, vibrational and rotational degrees of freedom. In ion imaging, the internal energy distributions are typically measured using laser-based techniques, that is resonance-enhanced multiphoton ionization, although laser-induced fluorescence imaging has been employed as well.

Simultaneous measurement of all the above quantities, as achieved by ion imaging, is important so that correlated quantities (e.g. the quantum state of one product correlated with that of the other, or the velocities of fragments correlated with the particular quantum state populated) can be determined. A further elegant aspect of the imaging technique is that the recoil of the fragments and/or reaction products is visualized by the ion images appearing on a phosphor screen. In this way the ion imaging technique provides instructive and direct ‘snapshots’ of the breaking and making of chemical bonds.

Experimental Aspects

Figure 1 shows a schematic of an ion imaging apparatus. The basic experimental components of an ion imaging instrument are (1) molecular beams used to collisionally cool the reactants and to generate reactants with a well-defined velocity; (2) lasers used to photolyse or generate the primary reactants, and to ionize the reaction product quantum-state-selectively; (3) two-dimensional time-of-flight mass spectrometry used to measure the recoil of the reaction products; and (4) a position-sensitive

Figure 1 Schematic diagram of an ion imaging apparatus (TOF = time of flight). Reproduced with permission from Heck AJR and Chandler DW (1995) Imaging techniques for the study of chemical reaction dynamics. *Annual Review of Physical Chemistry* 46: 335–378. © 1995 Annual Reviews Inc.

detector used to detect two-dimensional time-of-flight profiles. The position-sensitive detector typically consists of a pair of chevron-type microchannel plates (MCP) coupled to a phosphor screen and a charge-coupled-device (CCD) camera. The CCD camera records the images appearing on the phosphor screen.

A typical photofragment imaging experiment starts when a jet-cooled molecule absorbs a laser photon, eventually leading to dissociation. The usual short (~ 3 ns) and focused laser pulse provides a well-defined starting point in time as well as in space for the experiment. Following the bond cleavage, the nascent fragments start to fly away from that point on spheres. Before the fragments recoil far away, the products of interest are selectively ionized using REMPI. Ionization does not change the recoil of the fragments significantly. The ions are extracted from the reaction region and transferred to the position-sensitive detector through a field-free time-of-flight region. During their flight to the detector, the spheres expand significantly. The flight-times of the fragments, and thus also the physical size of the spheres upon reaching the detector, can be adjusted experimentally by varying the extraction field strengths in the time-of-flight region. On arrival at the detector, the three-dimensional distribution of the ionized fragments is crushed onto the plane of the two-dimensional detector. The position where the ion impinges on the detector is directly fibre-optically coupled to a small spot on the phosphor screen. The light emitted by the phosphor screen is detected by a CCD camera. The measured ion images are therefore two-dimensional projections of the three-dimensional velocity distributions.

Extraction of Information from the Images

Several methods can be used to analyse the ion images. The most straightforward approach, analysing the 'raw' images, already provides insight into the dynamical processes involved in the photofragmentation. The two-dimensional projections may reveal different channels involved in the reaction; however, branching ratios cannot be determined quantitatively when contributions of competing channels spatially overlap in the image. Two-dimensional projections show qualitatively the angular distributions of the recoiling fragments. Knowledge of the time of flight of the ionized fragment, the masses of the two concomitant fragments, the photolysis laser wavelength and the bond energy in the parent molecule provides information about the translational and internal energy of the complementary fragment.

More quantitative information can be obtained from the images when the full three-dimensional speed and angular distributions are reconstructed using mathematical transformations of the crushed two-dimensional images, or alternatively by using forward convolution simulation techniques. If the initial three-dimensional distribution has cylindrical symmetry, a *unique* transformation – the inverse Abel transform – can be used to reconstruct the initial three-dimensional velocity distribution. As the photolysis laser vector defines automatically an axis of cylindrical symmetry, the inverse Abel transformation can usually be used, as long as the plane of the position-sensitive detector is placed parallel to the laser polarization vector.

The angular distribution of photofragments depends particularly on the symmetry of the electronic transition

and the direction of the photolysis laser polarization vector. The angular distribution of photofragments is usually described by the anisotropy parameter β . In particular, the recoil distribution, which is related to the velocity of the fragment v and the polarization vector of the electromagnetic field E , is given by

$$I(\theta) = (4\pi)^{-1}[1 + \beta P_2(\cos \theta)] \quad [1]$$

where θ is the angle between v and E , P_2 is the second-order Legendre polynomial and β is the anisotropy parameter. This anisotropy parameter β may range from -1 for a perpendicular transition, that is μ perpendicular to E , resulting in a $\sin^2(\theta)$ distribution of the photofragments and 2 for a parallel transition (which results in a $\cos^2(\theta)$ distribution). $\beta = 0$ corresponds to an isotropic distribution of the fragments. **Figure 2** shows schematic representations of three-dimensional distributions of photofragments resulting from prompt dissociations following a parallel transition (**Figure 2a**) and a perpendicular transition (**Figure 2b**). Following a parallel transition, the fragments will recoil primarily along the laser polarization vector, whereas following a perpendicular transition, the fragments recoil perpendicular to the laser polarization vector.

Figure 3 shows a series of reconstructed ion images of nascent D (deuterium) atoms generated via the photolysis of DI, at three different photolysis wavelengths. These images can be used to illustrate many of the points made above. The upper panels show the inverse Abel-transformed ion images, the lower panels the corresponding D atom speed distributions. What information is inherent in the ion images of **Figure 3**? If the nascent D fragments had not acquired any kinetic energy following the photodissociation, the ionized D^+ ions would have shown up at the centre of the image. From the measurement of the size of the rings and arrival time of

the ions at the detector, the speed of the D atoms may be determined. It is immediately clear that the speed of the nascent D atoms is much higher when DI is photolysed using $\lambda = 205$ nm photons instead of $\lambda = 308$ nm photons, since the ion image obtained at $\lambda = 308$ nm is smaller. From these measurements and knowledge of the photolysis energy (or laser wavelength), the bond dissociation energy of the DI molecule may be determined. The photodissociation of HI or DI is possibly one of the simplest, but also most-studied, dissociation processes. At ultraviolet wavelengths two product channels are energetically accessible:

where $\text{I}(^2\text{P}_{3/2})$, or I , is ground-state atomic iodine and $\text{I}(^2\text{P}_{1/2})$, or I^* , is the spin-orbit excited state of iodine, which is 0.94 eV higher in energy than the ground state. Therefore, two distinct D atom translational energies are possible corresponding to the concomitant formation of the two different spin-orbit states of the iodine atom. From analysis of the inverse Abel-transformed ion images we can directly obtain the I/I^* branching ratios for the dissociation, and moreover the angular distributions of the D atoms for the two channels individually. The three images presented in **Figure 3** reveal that the branching ratio between the I and the I^* channel changes quite dramatically with photolysis energy. At low energy, only the I channel is observed and a single ring is seen that corresponds with a pure $\sin^2(\theta)$ angular distribution. As the energy is increased, the I^* channel becomes energetically accessible and an additional component, corresponding to a $\cos^2(\theta)$ distribution, is seen in the images. This example of imaging of D atoms from the photolysis of DI reveals the general capabilities of the technique. In a single measurement, many valuable parameters that characterize a molecular dissociation, such as product branching ratios, angular distributions of the nascent fragments and bond dissociation energies, are revealed. Photofragment ion imaging has been applied to many molecular systems, in most cases revealing exciting new aspects of the dynamics governing molecular photodissociations.

Figure 2 Schematic diagram of the three-dimensional distributions of photofragments formed following (a) a pure parallel transition in the precursor molecule and (b) a pure perpendicular transition in the precursor molecule. The arrows indicate the direction of the laser polarization vector.

New Developments

Ion imaging is now, some 20 years after its introduction, a well-established tool for the study of molecular reaction dynamics. There has been remarkable progress in the field, in particular in the areas of velocity resolution and photoelectron imaging, complex photodissociations of polyatomic molecules exhibiting many competing reaction pathways, and reaction product imaging of bimolecular reactions.

Figure 3 Inverse Abel-transformed ion images and speed distributions of D atoms formed in the UV photolysis of DI at three different photolysis wavelengths. The faster fragments will have recoiled farther from the centre of the image. For the images obtained at photolysis wavelengths $\lambda = 205$ nm and 243 nm, the outer rings correspond with the formation of D atoms concomitantly with ground-state I atoms, whereas the inner rings correspond with the formation of D atoms concomitantly with spin-orbit excited-state I^* atoms. At a photolysis wavelength $\lambda = 308$ nm, only ground-state I is formed concomitantly with the D atoms. Intensities are shown in a linear grey scale (darker corresponds to higher intensities). Reproduced with permission from Heck AJR and Chandler DW (1995) Imaging techniques for the study of chemical reaction dynamics. *Annual Review of Physical Chemistry* 46: 335–378. © 1995 Annual Reviews Inc.

Energy Resolution, ‘Velocity Mapping’

Parker and Eppink have introduced a modification to the ion optics in ion imaging instruments employing a set of electrostatic lenses. The modified setup does not require grids, which were typically used to cover the large holes (of approximately 20 mm diameter) in the extractor plates, to ensure parallel field lines (see **Figure 1**). Such grids may cause ‘grid distortions’ in the measured ion images. Another problem encountered in the original photofragment ion imaging instruments stemmed from the interaction region between the molecular beam and the photolysis laser often being not, as desired, a point source but rather more a line source defined by the physical size of the interaction volume of the molecular beam and the laser beam. Line sources may cause ‘blurring’ of ion images. To reduce ‘blurring’ of the images, several computational ‘deblurring’ algorithms have been introduced. The experimental approach introduced by Parker and Eppink greatly diminishes blurring as it focuses all ions with the same initial velocity to the same spot (i.e. pixel) on the

MCP detector and therefore overcomes the need for computational deblurring routines. Focusing conditions are defined by the time-of-flight path length and the ratio of the voltages applied to the repeller and extractor plates. Parker and colleagues demonstrated the improved capabilities of the modified ion imaging apparatus, investigating complex competing pathways in photoionization and dissociation of molecular oxygen, excited to the $v = 2$, $n = 2$ level of the $3dp^3\sum_{1g}^-$ Rydberg state. By absorbing a subsequent photon, these excited intermediate states of molecular oxygen may (a) dissociate generating ground-state and excited-state oxygen atoms (the latter being ionized by a subsequent photon), (b) autoionize forming O_2^+ ions in ground or excited states, (c) autoionize and dissociate forming O^+ and ground-state and excited-state O atoms, or (d) autoionize and dissociate after absorption of one more photon. In total, more than 10 different channels are expected, which normally would hamper any sort of analysis.

An interesting advantage of imaging instruments is that they may be converted, without major modifications,

Figure 4 Photolysis and ionization of O_2 through the $v=2$, $n=2$ level of the $3\text{d}^3\sum\bar{1}_g$ Rydberg intermediate state. The figure on the left shows a raw O^+ ion image, whereas the figure on the right shows the corresponding photoelectron image. The positions of rings that correspond with O_2^+ vibrational levels and excited O^* atoms are indicated in both images. The laser polarization vector was vertical for both these images. Intensities are shown in a linear grey scale (darker corresponds to higher intensities). Reproduced with permission from Parker DH and Eppink AJJB (1997) Photoelectron and photofragment velocity map imaging of state-selected molecular oxygen dissociation/ionization dynamics. *Journal of Chemical Physics* 107: 2357–2362.

to photoelectron imaging instruments as described by Helm and co-workers, providing an alternative method of angle-resolved photoelectron spectroscopy. Owing to the enhanced resolution and by combining results of the O^+ images with the images of the corresponding photoelectrons, Parker and Eppink were able to unravel the relative importance of most of the anticipated channels, all exhibiting different kinetic energy releases and different angular recoil. **Figure 4** shows on the left the ion image of the O^+ ions and on the right the corresponding image of the photoelectrons. The positions of the rings corresponding to the formation of O^* atoms are indicated, as well as the positions of the rings involving intermediate $\text{O}_2^+(v)$ states. Channels separated by less than 100 meV in kinetic energy are still quite well resolved. This improvement, brought about by a relatively simple modification, increases the resolution in the images tremendously and is expected to enhance the capabilities of photofragment ion imaging ever more.

Ion Imaging of Complex Polyatomic Photodissociations

The first ion imaging study, by Chandler and Houston, focused on the molecular dissociation of CH_3I . Although this is a relatively large polyatomic molecule, its dissociation behaviour is comparatively simple as far as possible reaction products are concerned, in that the

$\text{H}_3\text{C-I}$ bond cleavage is by far the most dominant process. One of the most notable features of ion imaging is the capability to distinguish different competing reaction pathways even when they produce the same products. The study of complex vacuum ultraviolet (VUV) photolysis of methane benefited greatly from the multiplex detection capabilities of ion imaging described by Zare. Considering only spin-conserving dissociation channels, reactions [3] are energetically accessible following VUV absorption:

Many of these five channels lead to one or more identical reaction products, and the contribution of all these pathways to the VUV photolysis could only be unravelled using the ion imaging technique. $\text{H}_2(v, J)$ photofragment images revealed that the two channels leading to molecular hydrogen in the photolysis of methane were indeed active. The rovibrational distributions of the $\text{H}_2(v, J)$ products were determined using REMPI, and by combining REMPI with the imaging technique for each

of these two channels individually. Similarly, H atom photofragment images revealed the relative contributions of the pathways leading to atomic hydrogen products.

The group of Reisler has employed ion imaging to study the dynamics evolving on the S_0 and S_1 excited states of isocyanic acid (HNCO). The unimolecular decomposition of HNCO is equally complex as it involves coupling between different electronic surfaces and competition among different reaction pathways. Following ultraviolet absorption, the HNCO molecule dissociates via the pathways in eqn [4].

Although the formation of triplet NH is the least endothermic reaction path, this channel is formally not allowed. However, this spin-forbidden channel has been observed. Initially, the two latter channels contributing to the formation of ground-state CO molecules, concomitant with triplet and singlet NH respectively, were identified using laser-induced fluorescence of the singlet and triplet NH separately. However, such an approach does not allow the identification of the relative branching ratios of these two channels, unless the transition strengths of the probed transitions are known quantitatively. Therefore, Reisler and colleagues studied the formation of ground-state CO by photofragment ion imaging, using state-selective REMPI on $\text{CO}(v=0, J)$. Probing only the CO fragments, the two channels are not resolved spectroscopically, but they can be resolved in velocity space using ion imaging: the two different reaction pathways lead to different velocities of the CO molecules. **Figure 5** shows an ion image obtained for CO with zero quanta of vibration and 10 quanta of rotation. $\text{CO}(v=0, J=10)$ fragments are formed concomitantly with triplet as well as singlet NH. Singlet NH is approximately $12\,500\text{ cm}^{-1}$ higher in energy than triplet NH. The singlet pathway leads to the smaller, somewhat more intense image, as less energy is available following this decomposition pathway, whereas the triplet channel leads to the bigger image, that is higher average speed of the CO molecules. As in the methane study, inverse Abel transformation of the images allowed the determination of rotational distributions of the CO fragments formed via these separate channels.

Reaction Product Ion Imaging

Photofragment ion imaging is now an established method for the measurement of photofragment velocity (speed and angle) distributions from unimolecular dissociation processes. The domain of the ion imaging technique has been

Figure 5 Ion image of CO ($v=0, J=10$) formed in the photolysis of HNCO at $\lambda=230.1\text{ nm}$. The outer part of the image originates from CO molecules formed concomitantly with triplet NH, whereas most of the CO molecules in the inner, more dense area of the image originate from CO molecules formed concomitantly with singlet NH. Intensities are shown in an inverse linear grey scale (darker corresponds to lower intensities). Reprinted with permission of Elsevier Science-NL from Droz-Georget T, Zyrianov M, Reislev H, and Chandler DW (1997) Correlated distributions in the photodissociation of HNCO to $\text{NH}(a^1\Delta) + \text{CO}(X^1\Sigma^+)$ near the barrier on S_1 . *Chemical Physics Letters* 276: 316–324.

expanded to investigate bimolecular reactions as well, with the aim of determining differential cross sections in a single measurement. Houston and colleagues have studied the inelastic scattering reaction of NO molecules off argon atoms. In this study, a molecular beam of NO was crossed with a molecular beam of argon. The scattering of NO molecules was investigated for NO products in selected rotational and spin-orbit levels. The scattering of NO was visualized directly using the reaction product imaging technique, through selective ionization of the selected NO quantum state, and appeared to vary quite dramatically depending on the J level of the NO product.

Chandler and colleagues studied the bimolecular reaction $\text{H} + \text{D}_2 \rightarrow \text{D} + \text{HD}$. In their study, an atomic hydrogen beam (generated through the photolysis of HI) of well-defined velocity was crossed with a molecular beam of D_2 . The velocity distribution of the deuterium atoms formed in the reaction was studied at two different centre-of-mass collision energies of 0.54 and 1.29 eV. **Figure 6** shows the D atom reaction product images at these two collision energies. The circles represent the maximum speed the D atoms could have, corresponding to the concomitant formation of HD in its rotational and vibrational ground states. It is directly obvious from these images that the nascent D atoms are predominately forward scattered with respect to the direction of the H atom beam velocity. The differential cross sections obtained from the inverse Abel-transformed images for the

Figure 6 Raw images of D atoms formed in the reaction of $\text{H} + \text{D}_2$. Intensities are shown in an inverse linear grey scale (darker corresponds to lower intensities). The left and right columns show results obtained for this reaction at centre-of-mass collision energies of 0.54 eV and 1.29 eV, respectively. In the images, the centre-of-mass (CM) of the reaction and the direction of the H atoms are indicated. The circles indicate the calculated positions of the fastest D atoms corresponding to formation of HD in the $v=0, J=0$ state. At the bottom of the figure the differential cross sections, obtained from the inverse Abel-transformed images are displayed. $\text{H} + \text{D}_2 \rightarrow \text{D} + \text{HD}$ reaction at these two different collision energies agreed fairly well with theoretically predicted differential cross sections. Reaction product imaging offers several advantages over more traditional methods used to study bimolecular reactive scattering in that the differential cross sections of the products, possibly in a single selected quantum state, are obtained in a single measurement.

Symbols

E	energy
$\mathcal{E}$	energy parameter depending on the experimental setup
E_0	initial energy of electrons
$I(0)$	intensity on resonance
$I(\infty)$	intensity off resonance
$I(\mathcal{E})$	intensity of the detected radiation
$I(v)$	intensity at any velocity v
$I(v_i)$	amplitude line at v_i position
$I(v, v_i)$	experimental spectrum SEDMS
$[\hat{J}]_{t_a, t_s}$	information matrix element of interest
$J^a(E)$	absorption line
$J_M(E)$	emission line
$L(E - \varepsilon)$	instrumental line
R	energy resolution
t_a	effective thickness of the sample
v	relative velocity
γ_{cr}	angle of total reflection
Γ	full width at half maximum
Γ_{nat}	natural line width
δ	isomer (chemical) shift
$\varepsilon(0)$	resonance effect magnitude
θ	direction electrons leaving the scatterer with an energy E
$\mu_a(E)$	total linear absorption coefficient
$\xi(\mathcal{E})$	noise due to the stochastic processes
$\varphi(E)$	function describing the response of the substance under investigation to monochromatic radiation

To obtain the Mössbauer spectrum the radiation from a Mössbauer source should be directed onto the sample under study. In Mössbauer experiments it is not the absolute energy of the γ -quanta which is determined but the energy shift of the nuclear levels. The energy scanning is carried out by the use of the Doppler effect and the energy parameters (Γ , δ) are expressed in velocity units, $v(E v/c)$. The Mössbauer spectrum is a measure of the dependence of the total intensity of radiation $I(v)$ registered by a detector in a definite energy region on the relative velocity v of the source.

A schematic diagram of a Mössbauer experiment and the spectrum is shown in Figure 1. If both the source and

the absorber are characterized by single lines of natural width Γ_{nat} , δ being zero, the spectrum will show maximum absorption at $v=0$. In this situation the intensity, $I(0)$, registered by the detector is minimized (Figure 1c). When the source moves at a certain velocity v , the emission line $J_M(E)$ is displaced relative to the absorption line $J^a(E)$. The overlap then decreases and the intensity increases. Finally, at a velocity that may be considered to be infinitely large ($v=\infty$), the spectrum overlap becomes so small that any further increase in velocity will not result in a significant increase in relative intensity. This value of intensity may be described as $I(\infty)$. The fact that the line shapes of the source and absorber are described by Lorentzians causes the experimentally observed line for a thin absorber to be Lorentzian, and its half-height width is the sum of the line widths of the source and the absorber.

Figure 1 Schematic illustration of the experimental arrangement (a) used to obtain a Mössbauer spectrum (c) for a single Lorentzian line both in the source and in the sample (b).

A typical device for accumulating the Mössbauer spectrum is the multichannel analyser, where the count rate is a function of a definite value of the Doppler velocity. The count rate is normalized relative to the off-resonance count rate. Hence, for transmission-mode Mössbauer spectroscopy relative intensities are always less than unity (or 100%). In Mössbauer scattering experiments relative intensities always exceed 100% and can reach several hundred percent in the case of electron detection from samples with a high abundance of the resonant isotope. It is most often that the $-v_{\max}$ value corresponds to the first channel and the $+v_{\max}$ value to the last channel. The quality of a Mössbauer spectrometer is determined by how accurately the modulation of the γ -quanta energy follows the chosen mode of movement.

Typical Mössbauer Spectrometers

The Mössbauer experiment may be in transmission mode, where γ -quanta are detected. The detector registers not only the γ -rays of the Mössbauer transition, but also the background noise. The main process competing with resonance interactions in the transmission mode experiments is the photoelectric effect. In transmission experiments there are three sources of background: (i) γ - and X-rays of higher energies which may be Compton-scattered; Bremsstrahlung produced outside the detector may contribute to this too; (ii) high-energy γ - and X-rays having lost only a part of their energy in the detector; (iii) X-rays that are not distinguished by the detector from the Mössbauer quanta.

In scattering Mössbauer spectroscopy the processes competing with Mössbauer scattering are the Compton effect, Rayleigh scattering and classical resonant scattering of γ -rays. The Compton effect is to be specially taken into account when the source emits high-energy γ -rays in addition to the Mössbauer radiation. The typical experimental arrangements are presented in Figure 2.

In Mössbauer spectroscopy the shape of the spectrum and its area are the 'signals' conveying quantitative information on a phase. When the shape is known to be Lorentzian, for example, the amplitudes and the line positions are often used as parameters of the signal $-I(v_i)$ value at v_i ($i = 0, 1, \dots$).

Mössbauer scattering spectra, obtained by detection of the γ -quanta or X-rays emitted out of the bulk of a material, convey information on the layer with a depth which is determined by the total linear absorption coefficient $\mu_a(E)$. The values of $\mu_a(E)$ for γ -rays and X-rays are generally different; therefore the Mössbauer spectra correspond to the layers, which are different in depth (from one to several micrometres). Backscattering Mössbauer spectroscopy is the most promising technique for applied research and industrial applications (see

Figure 2 Experimental arrangements and Mössbauer spectra for a ^{57}Co (Cr) source and a sample of $\alpha\text{-Fe}$: (a) transmission geometry, (b) scattering geometry with the detection of γ - or X-rays, (c) backscattering geometry with the detection of X-rays and electrons. The source moves at a velocity v .

Figure 2c). The backscattering geometry is simple, efficient and suitable for any type of radiation. In such an experiment one can detect any radiation in different scattering channels. However, to detect γ -quanta, a special detector is needed. It has been shown by many experimentalists that the signal/noise ratio of the detection of γ -rays in the experimental geometry of Figure 2b is better than for detection of X-rays. At the same time the flat proportional counter has never been used to detect γ -quanta in the backscattering geometry of Figure 2c. Indeed, the direct Mössbauer radiation of an intensity which is 100 times as high as the scattered intensity also passes through the detector such that the effect would be very small. The need to detect the resonantly scattered γ -quanta in a solid angle close to 2π stimulated the search for a detector capable of sensing scattered photons with an energy of 10–20 keV and which would be insensitive to the direct primary beam of γ -quanta.

The requirements have been met by the use of toroidal detectors. The main problem has involved the necessity to create the inner electric field with circular equipotential lines around the anode. For this purpose, one uses cylindrical grid wires surrounding the anode. Electrons produced within the counter volume travel to the grid and through it to the anode wire. After filling with a krypton–methane mixture the resolution for the 14 keV line for

such a counter is $\sim 15\%$. A section of a Mössbauer spectrometer using the counter is shown in **Figure 3**. This toroidal proportional detector is easy to handle and can be usefully applied to surface studies with high efficiency.

Conversion Electron Mössbauer Spectroscopy

Mössbauer transitions are usually highly converted and are followed by the emission of characteristic X-rays and Auger electrons. (The total internal conversion coefficient is high. For most cases de-excitation of the nucleus is via the emission of conversion electrons followed by rearrangement of the excited atomic shell by X-ray emission and Auger processes. More than one electron is produced per resonant scattering event.) The detection of electrons has proved in many cases to be the most efficient means of observing the Mössbauer effect. The principal feature of Mössbauer spectroscopy based on the detection of electrons is that the average energy of an electron beam reaching the detector, and also the shape of the energy spectrum, depends on the depth x of a layer dx from which the beam has been generated. This provides interesting possibilities for layer-by-layer phase analysis. Various modifications of Mössbauer spectroscopy based on the detection of electrons have been developed including a technique which allows the

Mössbauer signal from a very thin surface layer (~ 3 nm) of a homogeneous bulk sample to be distinguished. The techniques in this field of Mössbauer spectroscopy are classified as either integral or depth-selective.

The integral technique is called conversion electron Mössbauer spectroscopy (CEMS). In CEMS, of prime interest is the probability that electrons originating from a layer dx at a depth x with energy E_0 leave in a random direction from the surface with any energy and at any angle and will be registered by a detector. The electrons may be divided into several groups: conversion electrons, Auger electrons, low-energy electrons resulting from shake-off events and secondary electrons resulting from the re-emitted Mössbauer quanta and the characteristic X-rays. The energies and relative intensities of the first two groups of electrons for ^{57}Fe and ^{119}Sn are given in **Table 1**.

The development of CEMS as an independent analytical method came as a result of the development of gas-filled proportional counters for the detection of electrons. **Figure 4** illustrates the operating principle of such a CEM spectrometer. The proportional counter in CEMS detects all the electrons in the energy interval from approximately 1 keV up to the Mössbauer transition energy. In addition to the high efficiency, the proportional counters have an energy resolution allowing, if needed, a certain depth selectivity to be obtained.

Phase analysis of multiphase mixtures, fine particles and disordered substances, as well as surface studies, require Mössbauer spectra to be recorded over a wide range of temperatures. The problem of the counter operation at temperatures other than ambient has received significant attention in Mössbauer spectroscopy. The counters can operate CEMS at low temperatures near 4.2 K and up to 1100 K.

Arrangements based on proportional counters which allow an independent and simultaneous recording of CEM spectra and X-ray Mössbauer spectra in back-scattering geometry, and γ -ray absorption spectra in transmission, have been developed for industrial application purposes, see **Figure 5**. Owing to the different escape or penetration ranges of the three radiations involved, the spectra give information on phases, depth and orientation. From a practical point of view the counters

Figure 3 Spectrometer based on the toroidal detector.

Table 1 Main radiation characteristics for the ^{57}Fe and ^{119}Sn de-excitation

Type	^{57}Fe		^{119}Sn	
	Energy (keV)	Probability per de-excitation (C_i)	Energy (keV)	Probability per de-excitation (C_i)
K-conversion	7.3	0.796		
L-conversion	13.6	0.09	19.6	0.83
M-conversion	14.3	0.01	23.0	0.13
KLL Auger	5.4	0.543		
LMM Auger			2.8	0.74

for γ -rays, X-rays and electrons must be separated and shielded to ensure independent detection.

In addition to the proportional counters, other types of gas-filled detectors are used in CEMS. First was the parallel-plate avalanche counter. In Mössbauer spectroscopy such detectors have been used as resonance detectors and at higher counting rates. These counters have found application in surface studies and are an effective tool for the registration of low-energy

($E < 1$ keV) electrons, which are practically impossible to detect with the proportional counter. Because of the high electron-detection efficiency this enables the measurement of reasonable spectra in a relatively short time for ^{57}Fe , ^{119}Sn , ^{151}Eu , ^{161}Dy and ^{169}Tm . Second, scintillation detectors may be considered. Thin organic (crystal or plastic) scintillators are used for detecting electrons. Gas scintillation proportional counters with a good energy resolution (e.g. $R \approx 8\%$ at 6 keV) may also be constructed for CEMS as well as semiconductor detectors.

Channeltrons, microchannel plates and windowless electron multipliers constitute a special group of detectors for CEMS. These have no entrance windows and are designed for vacuum operation which can be used to advantage in CEM spectrometers operating at both high and low temperatures. A new method of surface study has recently appeared, CEMS based on the detection of very low-energy electrons. Detectors in this group have no energy resolution. The pulse-height distribution at the output of these detectors is similar to the noise distribution.

Advantages of the best CEM spectrometers with a channeltron include their easy sample access, high cooling rate, capability of simultaneous transmission measurements and adaptability to on-line experiments. To increase the count rate, detection efficiency or the effect value, a bias potential is sometimes applied to the sample or to the input of the channeltron. The statistical quality of spectra is, as a rule, nearly as good as for the gas-filled ionization detectors. The effective technique of collecting secondary electrons by applying a bias potential between the sample surface and a channeltron has been used to develop a spectrometer for low-temperature

Figure 4 Schematic picture of a spectrometer for back-scattering studies.

Figure 5 Setup for simultaneous recording of CEM spectra (1), X-ray Mössbauer spectra (2) and transmission spectra (3).

measurements (see **Figure 6**). The beam of γ -quanta is incident at 45° to the sample surface. The sample is the first electrode in a system of electrodes used to attract the secondary electrons to the entrance of the channeltron and to accelerate them to an energy corresponding to the maximum detection efficiency.

Low Energy Electron Mössbauer Spectroscopy (LEEMS)

Conversion electrons, KLL, KLM and KMM Auger electrons, photoelectrons and Compton-scattered electrons which are produced by γ -rays (with the energy above several hundred eV) in this context may be

Figure 6 CEM spectrometer used to operate at 4.2 K. M, mylar window, B, cold finger. The detection assembly is screwed on to the dewar at SS'.

regarded as 'high energy' electrons emitted by the atom. Secondary electrons result from the interaction of the above electrons with matter. Also, there are electrons that are primarily produced with a very low energy. Two processes contribute to the intensity of the electrons. These are very low energy Auger electrons (LMM, MMM, MMN) and shake-off electrons.

Experimental data show a sharp peak in the number of electrons (related to Mössbauer events) at energies below 20 eV. These electrons supply information on a surface layer to a depth of ~ 5 nm. The detection of very low energy electrons offers the advantage of short data acquisition times ($\sim 77\%$ of the electrons emitted from the Fe atom are low-energy Auger and shake-off electrons), and increases surface sensitivity compared to established procedures relying on the collection of electrons near 7.3 keV. CEMS detectors and techniques are summarized in **Table 2**.

Depth-Selective Conversion Electron Mössbauer Spectroscopy

The detection of electrons with energy E by a β -spectrometer with high-energy resolution gives a Mössbauer spectrum corresponding to the phase at a depth x_1 in the scatterer. If the known relationship between the energy of detected electrons and the depth of the layer through which they have passed is used, then depth-selective analysis of the surface layers can be performed. In depth-selective conversion electron Mössbauer spectroscopy (DCEMS) the group of electrons with a fixed energy leaving the surface at a certain angle within a small solid angle $d\omega$ is of interest.

There are a number of electrostatic and magnetic electron spectrometers that have been used, designed and developed for DCEMS. A schematic description of the DCEM spectrometer, based on the mirror analyser, is depicted in **Figure 7**. Electrons, starting from inside the inner cylinder at angles close to 45° to the sample surface (1 cm^2), move out through slits in the inner grounded cylinder into a strong field region. The field bends the trajectories of the electrons back towards the inner

Table 2 Detectors and electron detection techniques in CEMS

cylinder. The group of electrons of interest passes through another slit, to be collected on the spectrometer axis. If a position-sensitive detector is placed on the axis, a series of Mössbauer spectra corresponding to different electron energies can be recorded simultaneously. Using three slits enables the simultaneous recording of K-, L- and M-conversion electron spectra.

An important methodology problem in DCEMS is the measuring time. For ^{57}Fe only the K-conversion electrons lead to a DCEMS spectrum. The thickness of the analysed layer in DCEMS is significantly less than in CEMS, being less than 80 nm for iron. It is dependent on parameters of the β -spectrometer. The resolution enhancement from 3% to 1% is significant for experiments involving the investigation of surface layers 0–5 nm thick. To investigate a thinner layer (0–2.5 nm thick), the β -spectrometer should detect separate groups of electrons in the 7.2–7.3 keV interval, and it is desirable to have $R \approx 0.5\%$ and $\theta \approx 90^\circ$. The maximum possible selectivity can probably be attained with electrostatic β -spectrometers whose accuracy of energy determination is about 1 eV and the half-width is ~ 10 eV on the 7.3 keV line. To summarize, the experimentalist in DCEMS should try to use a detector with an efficiency close to 100%. There should be no window in the path of the electrons. The temperature of the sample may be varied in the range 4.2–1000 K.

Special Mössbauer Spectrometers

There is a special situation where hyperfine interactions are present and a constant velocity v_i is chosen, so that the incident radiation is on resonance with the scatterer's line number 2 ($v_i = v_2$). There is, in this situation, no unique relation between the energies of the incident and scattered γ -quanta. The scattered quantum may have the

Figure 8 A schematic experimental arrangement used for selective-excitation double Mössbauer spectroscopy.

energy of the incident quantum, as well as the energy belonging to the line number 4. The same is true if relaxation processes or very complicated hyperfine interactions occur in the sample. To study the phenomenon the incident γ -quanta energy should be fixed and the energy spectrum of scattered γ -quanta will show directly the energy change of γ -quanta on scattering.

To obtain the energy distribution, a γ -ray detector is needed with an energy resolution of approximately Γ_{nat} . For this purpose a resonant filter is placed in front of the conventional detector (see **Figure 8**). This filter is a 'single line' Mössbauer absorber. Driving the filter ('analyser') in the constant acceleration mode and detecting the outgoing radiation allows the $I(v; v_i)$ spectrum to be produced (see **Figure 9**). The observed effect is determined now by the two elastic resonant scattering processes (by four f factors). Two synchronized drive systems are necessary to observe the two scattering processes. This is known as selective-excitation double Mössbauer spectroscopy (SEDMS).

The method is demonstrated by considering the SEDM spectrum recorded for scattering at the energy corresponding to the $-\frac{1}{2} \rightarrow -\frac{1}{2}$ transition in a $9 \mu\text{m}$ thick ^{57}Fe foil (**Figure 9**). The Mössbauer spectrum consists of the second and fourth lines of the usual spectrum of α -Fe, that is the lines corresponding to the $-\frac{1}{2} \rightarrow -\frac{1}{2}$ transition as well as to the $-\frac{1}{2} \rightarrow +\frac{1}{2}$ transition, where the quantum numbers refer to the nuclear spin levels.

The main advantage of SEDMS is that the method offers a direct means by which the relaxation processes between sublevels of the excited nucleus can be observed. Indeed, the experimental spectrum $I(v; v_i)$ gives direct information on time-dependent hyper-fine interactions which determine the nuclear level splitting. The relaxation times in the region of 10^{-7} – 10^{-10} s are the most

convenient to measure. Unfortunately, the necessity of having two successive resonant interaction processes results in a very low detected intensity. Indeed, the second part of a SEDMS experiment is a transmission experiment with the scatterer being the Mössbauer source.

Also, special Mössbauer spectrometers are used for total external reflection (TER) studies. On reflection at angles less than γ_{cr} the electromagnetic field intensity falls off rapidly (for the metal iron mirror, $\gamma_{cr} = 3.8 \times 10^{-3}$ sr). The penetration depth for the radiation (i.e. the thickness L of a layer under study) is taken to be equal to the depth at which the intensity is less by times e . If only the elastic scattering by electrons is considered, L is evaluated to be 1.3 nm for an iron mirror.

An experimental set-up is given for studies of TER of Mössbauer quanta in **Figure 10**. The design of the Mössbauer spectrometer for TER studies ensures: (1) simple and reliable setting and measurement of the grazing angle γ_{cr} ; (2) convenience in the adjustment of the angular beam divergence; (3) sample replacement without affecting the experimental geometry; (4) reproducibility of all source–collimator–sample distances; and (5) sample rotation in the range 0 – 90° . The spectrometer consists of the analytical unit and electronic system for control, acquisition and processing of spectrometric data.

Figure 9 SEDM spectrum of α -Fe.

The analytical unit of the spectrometer comprises a vibration damping platform suspended on shock-absorbers. Mounted on the platform are guides of the 'wedge slide' type, which carry the driver, shielding screens, collimator to form narrow directed plane-parallel radiation beams, proportional counter and scintillation detector. A narrow plane-parallel γ -ray beam from the source rigidly attached to the driver is formed by the slit collimator and, through the entrance window of the dual detector, falls on the sample. The γ -radiation is reflected from the sample surface and passed through the exit window of the dual detector and slotted mask (screen), and detected by the scintillation detector D1.

Although the analysed layer is very thin, the technique has not been widely used due to the very low luminosity. Of no less importance is the fact that interference effects complicate the interpretation of the experimental data. Substantial progress is achieved by detecting not only the mirror-reflected γ -quanta, but all secondary radiation leaving the surface when Mössbauer radiation is incident at an angle that is less than critical. The key part of an experimental set-up is the dual proportional counter (see **Figure 10**). A schematic picture of the dual-chamber gas proportional counter is shown in **Figure 11**. The sample under investigation is inside the electron chamber of the detector. The gas mixture in the chamber is He + 8% CH₄. The gas mixture for detection of γ - and X-rays is Ar + 8% CH₄. Thus during a single run (preset γ value) one can obtain four Mössbauer spectra simultaneously: three from the combined detector and one from the scintillation detector (mirror-reflected γ -rays).

Spectrum Quality and Quantitative Information from Mössbauer Spectra

The amplitude of Mössbauer lines in scattering experiments can often be greater than in a transmission geometry. However, the intensity loss of the scattered radiation of about two orders of magnitude makes it necessary to compare both the sensitivity of the two

Figure 10 An experimental setup for studies of total external reflection of Mössbauer quanta. D1, scintillation detector. $L_0 \sim 600$ mm, $L_1 \sim 700$ mm, $L_2 \sim 400$ mm, $h = (1 \pm 0.05)$ mm.

Figure 11 Part of an experimental setup (see **Figure 10**): the dual proportional counter.

methods and the quality of the two spectra obtained. For a thin sample characterized by a single Lorentzian and the effective thickness t_a , the quality of the spectrum in relation to the quantity of information on the t_a parameter (the information matrix element of interest), $[\hat{J}]_{t_a, t_a}$ is:

$$[\hat{J}]_{t_a, t_a} = \frac{\pi}{4} \varepsilon^2(0) I(\infty) \Gamma$$

where $\varepsilon(0)$ is the resonance effect magnitude. In order to increase $\varepsilon(0)$, the experimentalist needs to decrease the solid angle towards the detector and sample to prevent the source radiation from reaching the detector as a result of multiple nonresonant scattering in collimators and surrounding materials. This always gives a greater $\varepsilon(0)$ value, but the $I(\infty)$ value is decreased. The expression allows the evaluation of the limit when a further increase of $\varepsilon(0)$ values is no longer reasonable. After the optimal experimental conditions are chosen, the $\varepsilon^2(0)$ values are fixed for each sample under investigation. The quality of the spectrum is determined by the product $I(\infty)\Gamma$ and, as well as $I(\infty)$, it is also proportional to the measuring time.

In any spectroscopy, the intensity of the detected radiation may be written in the form:

$$I(\mathcal{E}) = C \int_{-\infty}^{\infty} L(E - \mathcal{E}) \varphi(E) dE + \xi(\mathcal{E})$$

where $\mathcal{E}$ is an energy parameter depending on the experimental setup, $L(E - \mathcal{E})$ is the instrumental line, $\varphi(E)$ is a function describing the response of the substance under investigation to monochromatic radiation, and $\xi(\mathcal{E})$ is the noise due to the stochastic processes.

In Mössbauer spectroscopy, any sample is characterized by $\mu_a(E)$. The simplest situation for recovering the $\mu_a(E)$ function from experimental data is in transmission spectroscopy, where $\varphi(E) = \exp[-\mu_a(E)d]$. There are

two ways to find the $\mu_a(E)$ function. The first involves a hypothesis concerning the nature of this function. Analysis of an experimental spectrum amounts to the determination of the parameters characterizing $\mu_a(E)$ in accordance with the hypothesis.

The second way is connected with natural assumptions only on the nature of the $\mu_a(E)$ functions, for example, their smoothness. If there are no grounds for choosing a hypothesis, a certain initial assumption is made as to the nature of the required function. This often amounts to a search for an expression describing the response of the medium to monochromatic radiation, and sometimes ‘an enhanced resolution of the method’ is spoken of. The idea is that the best quality of the spectrum is attained using a source with a line shape described by the δ -function. Some methods of enhanced signal recovery have been developed for Mössbauer spectroscopy. As in sensitivity or resolution enhancement in other types of spectroscopy, a compromise has to be made between sensitivity and line width, as increasing the resolution always causes a decrease in sensitivity. Other types of data processing have been used to minimize distortion introduced by the measuring instruments.

η_i	relative area (%) under the spectrum
$\Delta\eta$	inaccuracy of the η determination
θ	grazing angle
τ	lifetime of nuclear excited state
$\rho(0)$	electron density

The application of Mössbauer spectroscopy in diverse fields of qualitative and quantitative analysis is based on the ease with which hyperfine interactions can be observed. The information obtained from Mössbauer spectroscopy may be correlated with other methods by which hyperfine interactions can be examined such as NMR, EPR, ENDOR, PAC (perturbed angular correlations), nuclear orientation and neutron scattering. However, Mössbauer spectroscopy often proves to be experimentally simpler, more illustrative and an efficient method for studying applied problems. Mössbauer nuclei are ideal 'spies' supplying information on both the microscopic and macroscopic properties of solids.

Three factors may be identified as responsible for the widespread use of Mössbauer spectroscopy in both fundamental and applied research. First is the highest relative energy resolution $R \sim \Delta E/E$ and rather good absolute energy resolution $\Delta E \sim \Gamma_{\text{nat}}$ (the natural line width) (sometimes $\sim 10^{-9}$ eV). Secondly, the absolute selectivity of Mössbauer spectroscopy means that in each

experiment a response is registered from only one isotope of the element. Thirdly, Mössbauer spectroscopy has a high sensitivity that is determined by the minimum number of resonant atoms needed to produce a detectable response. In transmission Mössbauer spectroscopy for ^{57}Fe , a response is given by a monolayer with an area of the order of 1 cm^2 . Also important is the absence of any limitation on experimental conditions other than that the sample should be a solid.

Applications in Physics

Mössbauer spectroscopy offers a resolution sufficient to measure the effect of differing gravitational potentials on frequency or time as predicted by Einstein. The sign of the effect can be reversed by inverting the sense of travel over a fixed vertical path. Pound and Rebka measured the gravitational red shift in a 22-metre tower and observed a -5.1×10^{-15} shift in the γ -ray energy of ^{57}Fe . The source–detector setup was interchanged every few days to allow comparison of the results from a rising γ -ray beam to those from a falling one. When all of these measurements were combined, they yielded a result 0.9970 ± 0.0076 times the result predicted from the principle of equivalence.

There have also been some applications of Mössbauer spectroscopy in nuclear physics, to measure quadrupole moments of long-lived nuclear states by observing the orientation of a state at very low temperatures through the intensity ratios in a Mössbauer transition. The spectra for the case of the nuclear orientation in the $-\frac{11}{2}$ state of ^{119}Sn by a quadrupole interaction are shown in **Figure 1**. In this case no macroscopic orientation of the hyperfine fields is needed. At very low temperatures the hyperfine splitting of the $-\frac{11}{2}$ state leads to an alignment in the $+\frac{3}{2}$ state yielding different intensities of the two Mössbauer lines. The increase of the intensity of line A located at higher velocities is clearly seen in the 16 mK spectrum. This uniquely indicates that the quadrupole moments of the $-\frac{11}{2}$ state and of the $+\frac{3}{2}$ state have the same sign. From a theoretical fit to the data it was deduced that $Q_{11/2} = -0.13 \pm 0.04 \text{ b}$. The same principle is used for measurements of temperature below 100 mK, i.e. by a ^{151}Eu Mössbauer thermometer using an absorber of EuS.

Figure 1 Mössbauer spectra of the 23.9 keV transition in ^{119}Sn with a source of $^{119}\text{Sn}^{\text{m}}(\text{OH})_2$ (polycrystalline samples with one of the largest quadrupole splitting of ionic Sn^{2+} compounds) at 4.2 K and 16 mK and a $^{119}\text{Sn}:\text{Pd}$ (3 at% ^{119}Sn) absorber chamber at a temperature of about 1.3 K are shown. The $-\frac{11}{2}$ state decays by an M4 transition to the $+\frac{3}{2}$ state of ^{119}Sn , which itself decays to the $-\frac{1}{2}$ ground state with the 23.9 keV M1 Mössbauer transition. The source was cooled inside the mixing chamber of the $^3\text{He}/^4\text{He}$ dilution refrigerator specially designed for Mössbauer experiments. The weak line C at 1.5 mm s^{-1} is attributed to Sn^{4+} impurities in the source.

More than 99.5% of all applications of Mössbauer spectroscopy are connected with hyperfine interaction parameters and structure factor determinations. An example of a sophisticated application is the study of the low temperature properties of magnetic impurities in metals that have an antiferromagnetic exchange interaction (Kondo effect). In order to study the very low temperature behaviour of a Kondo system, Mössbauer spectroscopy was used on two ‘typical’ Kondo systems, $\text{Fe}:\text{Cu}$ and $\text{Fe}:\text{Au}$. The first system ($\text{Fe}:\text{Cu}$) showed expected Kondo-type properties – an extra polarization in the electron gas due to the correlations produced by the Kondo effect. The $\text{Fe}:\text{Au}$ system, on the other hand, exhibited quite unexpected and striking results incompatible with those for $\text{Fe}:\text{Cu}$. In brief, in $\text{Fe}:\text{Au}$ the temperature dependence of the susceptibility differed for $T > 10 \text{ K}$ from that for $T < 10 \text{ K}$, yielding $\theta_1 = 10 \text{ K}$ and $\theta_2 = 0.5 \text{ K}$ for the Curie–Weiss θ of the two temperature regimes. Some data at low temperature are given in **Figure 2**. All data show that $\text{Fe}:\text{Au}$ is clearly a system in which even at very low impurity concentrations the interaction effects are important at low temperatures and low external fields. Thus, it is difficult to extract parameters for the intrinsic Kondo behaviour of the isolated impurities from the experimental data on this system. The data show that the Kondo temperature for $\text{Fe}:\text{Au}$ is most likely in the order of

Figure 2 Mössbauer spectra of the source of $\text{Fe}:\text{Au}$, prepared by diffusing ^{57}Co into a foil of Au; the total impurity content ($\text{Co} + \text{Fe}$) was below 10 ppm. The source was attached to the mixing chamber of a $^3\text{He}/^4\text{He}$ cryostat. The absorber was iron potassium hexacyanide at 1.3 K in the same external field ($H_{\text{ext}} \leq 6.0 \text{ T}$). The solid lines are fits to the spectra including line broadening due to relaxation effects or a distribution of hyperfine field.

10 K and not 0.5 K; the lower temperature seems to be connected with some kind of magnetic order.

Mössbauer spectroscopy is especially fruitful if the effective field, H_{eff} , is one of the parameters determining the shape of the spectrum. H_{eff} is the resultant of the averaging of the hyperfine field H_n , but the way in which it is derived depends on the sample. The outcome is determined by comparing the frequency of the fluctuation of the H_n direction with the Larmor precession frequency of the nucleus in the hyperfine field. In a

ferromagnetic material, the temperature dependence of H_{eff} is predicted to be the same as the temperature dependence of the expectation value of the atomic spin, and consequently of the magnetization. It thus provides a method for investigating magnetization without the application of external fields.

The study of the magnetic properties of materials and the dynamic aspects of magnetic interactions have been the most frequent applications of Mössbauer spectroscopy. The latter can be done particularly conveniently in the case of single-domain particles. A reduction in the dimensions of single-domain particles increases the probability of thermal fluctuations of the magnetization orientations and this leads to superparamagnetic phenomena. One can suppress superparamagnetism either by cooling the sample or by applying an external magnetic field H_{ext} (see **Figure 3**). Such studies permit the determination of the magnetic anisotropy, the alignment of magnetic domains, the particle size, the magnetic interaction among microcrystals, and surface effects.

A final illustration of the application of Mössbauer spectroscopy in physics is the study of spin texture in amorphous metals. Mössbauer spectroscopy provides information on both magnetic anisotropy and the texture of the principal electric field gradient (EFG) axes that reflects crystallographic features of the solid-state structure. It is known that spin texture in glassy metal ribbons, formed by high-speed quenching of fluid metals, is extremely sensitive to strains and stresses. This is partly consistent with the very low crystalline anisotropy in these materials. The results of a study of $\text{Fe}_{80}\text{B}_{20}$ are presented in **Figure 4**. The Mössbauer spectra for the contact with the quenching support and noncontact surfaces of the band are different. These differences in magnetic properties of the surfaces are due to the different cooling conditions during the band production. As the result of texture determination by Mössbauer spectroscopy, a distribution function $D(\theta_m, \Phi_m)$ (see **Figure 5**) was found for the contact and noncontact surfaces of the band, which describes the distribution of the relative volumes wherein H_{eff} or the EFG are oriented along the (θ_m, Φ_m) direction in a unit solid angle. Consideration of **Figure 4** shows that the magnetic anisotropy is along the y -axis. Hence, the magnetic dissipation fields on the alloy surface are significantly weaker. This is indicative of the high magnetic quality of the surface of the $\text{Fe}_{80}\text{B}_{20}$ alloy. This means that the local environment of Fe atoms is the same for the two sides of the band, i.e. there is no difference in the concentrations of Fe atoms and the metalloid atoms.

Applications in Chemistry

The three components of the hyperfine interaction – the isomer shift, the nuclear quadrupole splitting and the

Figure 3 Spectra of microcrystals of Fe_3O_4 obtained at 260 K in various applied magnetic fields. The iron atoms at the octahedral and the tetrahedral sites in Fe_3O_4 have different hyperfine fields with opposite directions, and the corresponding Mössbauer lines are not completely resolved even in an external field of $H_{\text{ext}} = 1.22$ T.

nuclear magnetic dipole splitting – have immediate chemical application. The isomer shift δ measures the charge density of the atomic electrons at the nucleus and is therefore directly related to chemical bonding and covalency. The ligand field splitting energy Δ depends on the gradient of the electric field produced by the other ions in the lattice, i.e. it is related to the point symmetry of the lattice information. H_{eff} provides a sensitive tool for the detection of magnetically ordered states. Mössbauer spectroscopy is a major tool for studying the formation of new inorganic materials and probing structural and magnetic phase transformations in inorganic compounds.

Figure 4 Mössbauer spectra from a band of an amorphous alloy: (a) contact surface, (b) noncontact surface. In accordance with the foil preparation, the z principal axis is perpendicular to the foil surface, the x axis is along the band and the y axis is perpendicular to the rolling direction. The direction of the incident Mössbauer quanta is specified by the angles θ and Φ .

This can be demonstrated with some specific examples. As the first example, the participation of 3d and 4s electrons in the chemical bond of iron in a complex determines the total electron density at the Fe nucleus (see **Table 1**), and hence the isomer shift for the Fe complex. A change in the oxidation state influences the electron density at the nucleus in a major way, since such a change is usually associated with the removal (or the addition) of one or more valence electrons. Thus the two oxidation states differ in their outer valence electron number by an integer, and this results in a major difference in the isomer shift for the two oxidation states. This is illustrated in **Figure 6**, where the isomer shifts for monovalent, trivalent, and pentavalent gold complexes with various halide ligands are shown. The electron density $\rho(0)$ is the least in Au(I) compounds and the highest in Au(III) compounds. The spread in the isomer shift for the selected halide ligands is small within an oxidation state.

The ability to determine oxidation states is demonstrated in **Table 2** for the isomer shift data of fluorides of

neptunium for various oxidation states represented by the $5f^n$ configuration.

The ice produced by the slow freezing of solutions that contain Mössbauer atoms and the glass produced by their rapid freezing are also suitable for investigation by Mössbauer spectroscopy. Systematic Mössbauer examinations of ices were started with investigations of the polymorphic transformation that occurs in the ice as a result of changes in temperature. Detailed investigations showed how the structure of the ice formed depends on the rate of freezing, and how this affects the Mössbauer parameters measured on the frozen solution. If rapid freezing is applied to equilibrium solution systems in which the equilibrium shifts rapidly (within 1–2 s) and measurably as a result of the change in temperature, Mössbauer spectroscopy provides reliable information only if the temperature of thermostating before the freezing is close to the solidification point.

Research into nonaqueous solvents and solutions is also worth note. When metal salts are dissolved in various solvents, it is possible to study the coordination of the

Figure 5 Texture distribution functions $D(\theta_m, \Phi_m)$ for the band of amorphous alloy $\text{Fe}_{80}\text{B}_{20}$: (a) contact surface, (b) noncontact surface. The direction of the quantization axis is determined by the angles θ_m and Φ_m .

Table 1 Isomer shifts, electron configurations, and value of the electron density difference $\Delta\rho(0)$ for matrix-isolated Fe ions

Ion	Configuration outside Ar core	Isomer shift ^a (mm s ⁻¹)	$\Delta\rho(0)$ (au)
Fe^0	$3d^64s^2$	-0.75 ± 0.03	16.0
Fe^+	$3d^7$	$+1.77 \pm 0.08$	0.0
Fe^{2+}	$3d^64s$	$+0.26 \pm 0.05$	10.5

solvent molecules to the cation and the extent of association between the cation and its anion.

The phenomenon of spin transition (spin cross-over) is another example of a fruitful application of Mössbauer spectroscopy in chemistry. The phenomenon is observed in transition metal complexes with d^4 , d^5 , d^6 , d^7 and d^8 electron configurations. Depending on the ligand field splitting energy, Δ , relative to the mean spin pairing energy, E_p , the ground state of a particular transition metal complex shows either high-spin (HS) behaviour or low-spin (LS) behaviour. If $|\Delta - E_p| \sim k_B T$, both HS and LS spin states may coexist in thermal equilibrium: $\text{HS} \rightleftharpoons \text{LS}$.

Figure 6 Isomer shift scale for Au(I), Au(III), and Au(V) halides.

Mössbauer spectroscopy reveals distinct resonance lines for the individual spin states provided their individual mean lifetimes are comparable to or longer than the lifetime τ of the nuclear excited state. If one determines the area fractions of the spin states involved (which in most cases come close to the actual molar fractions of HS and LS molecules), one may follow quantitatively the spin conversion as a function of temperature. The simplest way to observe the transition is to change the temperature. An unusual way to affect the spin transition behaviour is to change the elastic properties of the crystal lattice, which are important for the spin transition behaviour. This was done by a partial isomorphous substitution of the central metal ions in mixed crystals of $[\text{Fe}_x\text{Mn}_{1-x}(\text{phen})_2(\text{NCS})_2]$ by

Table 2 Isomer shifts for the various fluorides of Np and the values of $\rho(0)$ for electron configurations, $5f^n$, nominally representing the oxidation states in fluorides

$5f^n$	Oxidation state	Electron density (au)	Isomer shift ^a (mm/s ⁻¹)

manganese ions, which differ in the volume and the electron configuration from the replaced metal ions (see **Figure 7**). The transition temperature shifts to lower temperatures upon dilution, and the residual paramagnetism at low temperatures increases systematically with decreasing iron concentrations x .

There are many other fields of application of Mössbauer spectroscopy in chemistry, including coordination chemistry, catalysis (heterogeneous), mixed-valence compounds, glasses, oxide and oxyhydroxide studies, and actinide chemistry.

Applications in Biology and Geology

Many biological molecules contain iron and Mössbauer spectroscopy is a useful tool for the study of proteins and enzymes. The measurement of the magnetic properties of transition metal elements in biological molecules by MS, NMR and EPR is an important way of characterizing the electronic state of the metal ion, and hence of providing a clue to the structure and function of the molecule. Mössbauer spectroscopy may be used to study their chemical state and bonding and to obtain qualitative data on the local structure and symmetry in their neighbourhood.

Haem proteins are the best-understood of these molecules, and the first systematic study of biological molecules using the Mössbauer effect was done on haemoglobin and its derivatives. Since then a great deal of work has been done on iron-sulphur proteins and on iron-storage proteins. Magnetic susceptibility data showed that the chemical state of the iron atom and its spin state are very sensitive to the nature of the sixth ligand. The Mössbauer spectra of these molecules have been valuable in confirming these earlier conclusions, and have yielded quantitative data on the way that the energy levels and wavefunctions of the iron atoms are affected by the ligand field and spin-orbit coupling in the protein. They have also been valuable in providing standard spectra for each of the four common states of

**Figure 7** Mössbauer spectra of $[\text{Fe}_x\text{Mn}_{1-x}(\text{phen})_2(\text{NCS})_2]$ at 5 K and various iron concentrations x . The spectra demonstrate that, with increasing dilution of iron by manganese, the intensity of the quadrupole doublet of the high-spin state of iron(II) (outer two lines) increases steadily at the expense of the low-spin quadrupole doublet of iron(II) (inner two lines).

iron, and a summary of the chemical shifts and quadrupole splittings measured at 195 K is shown in **Table 3**.

In disease, haemoglobin may become ferric (denoted metHb) and of low spin, e.g. in a haemoglobin cyanide metHbCN, azide metHbN₃ or hydroxide metHbOH. The most noticeable feature of the spectra is the appearance of magnetic hyperfine structure at 77 K. Spectra of metHbCN at these temperatures are shown in **Figure 8**. At 4.2 K the magnetic hyperfine spectrum is well resolved, but is complex and asymmetrical owing to the anisotropy of the hyperfine interaction tensor.

Apart from haem proteins, there are studies of iron-sulfur proteins, iron transport and iron-storage compounds, iodine compounds and vitamin B₁₂. There are

Table 3 Isomer shifts δ and quadrupole splittings ΔE_Q for haemoglobin at 195 K. The symbol metHb is used for ferric haemoglobin and Hb for ferrous haemoglobin

Figure 8 Mössbauer spectra of a low-spin ferric haemoglobin metHbCN – at (a) 195 K, (b) 77 K and (c) 4.2 K. The broadening at 77 K relative to 195 K is due to the slower electron spin relaxation rate. At 4.2 K the relaxation is so slow that the hyperfine pattern is resolved, but complex.

many publications connected with nitrogenase, oxygenase, hydrogenase and cytochrome P450–ferredoxin enzyme systems and medical and physiological applications.

Application of Mössbauer spectroscopy to crystallography, mineralogy and geology is very similar to chemical applications, with the main emphasis on phase analysis and structure determination. In view of the great importance of iron in the earth's crust and the widespread occurrence of this element in rock-forming minerals, earth scientists have naturally focused attention on

applications of ^{57}Fe Mössbauer spectroscopy. One of the most important groups of rock-forming minerals are the silicates, in which particular lattice positions are often occupied by more than two atomic species. In these cases, accurate site occupancy numbers for each species cannot be obtained by diffraction alone. Mössbauer spectroscopy has been a useful tool for investigating the local properties of iron sites in complex crystal structures, particularly when employed on minerals with carefully defined (well-known) positional parameters.

Typical applications of Mössbauer spectroscopy to mineralogy and geology have been analysis of the oxidation state of iron at iron sites in minerals. The ferric to ferrous iron ratio reveals important information on the partial pressure of oxygen during crystallization, which is a parameter of geological significance. The study of area ratios of distinct hyperfine patterns has led to thermodynamic analyses of order–disorder phenomena in minerals. Application of Mössbauer spectroscopy to poorly crystallized materials of geological relevance may be fruitful. Studies have been made on hydrolysis and absorption in clay minerals and on coordination polyhedra of iron in glasses.

Mössbauer spectroscopy has made a modest contribution to the study of composite samples and separated mineral phases from the moon. The constituents of the lunar soil are of a highly complex nature. The primary aim has been to study the amount of iron in the soil, the distribution of iron over the soil constituents, and the particular valence states. The soils at the moon landing sites do not represent averages of the collected rocks. The spectrum of the soil (**Figure 9**) is the superposition of patterns of ^{57}Fe in silicate minerals, silicate glasses, ilmenite, metallic iron, and troilite.

The identification of the magnetic patterns of metallic iron and FeS and the quadrupole-split pattern of paramagnetic FeTiO_3 is generally no problem in spectra from soil absorbers kept at room temperature (**Figure 9**). However, the paramagnetic silicates in the soil cannot be identified easily because of the substantial overlap of their quadrupole-split patterns.

Surface Layer Studies

Mössbauer spectroscopy has developed as one of the few methods available for investigation of solids differing in depth by several orders of magnitude. These can be layers with the depth of less than 1 nm (scattering at glancing angles) as well as layers that are about 10 μm deep (electron and X-ray detection). The technique is able to examine solids over a wide range of compositions, gaseous pressures, and temperatures and under conditions of practical interest. It should also be noted that Mössbauer spectroscopy is one of the best methods

for *in situ* characterization of solid–solid and solid–solution interfaces. This lends itself to *in situ* studies of surfaces under various coatings and processes, surface magnetism and the effect of the gas phase on the properties of the surface layers and the structure and magnetic properties of epitaxially grown monolayers on the surface of oriented single crystals. The techniques of

surface layer analysis find extensive applications in science and industry.

The thinnest layers to be studied in Mössbauer spectroscopy are those studied by GA DCEMS and (total external reflection) TER. For example, the TER method has been used to study the initial stage of oxidation of α -Fe foil. The substantial progress in surface studies using glancing angles was achieved by simultaneous detection of electrons, γ -rays or X-rays as well as mirror reflected γ -rays, which allows reconstruction of the process of surface layer formation. The sample under investigation was inside the electron chamber of the detector. The results of the calculation and the fitting of the experimental spectra are very sensitive to the model of surface layer structure and to the density of the top layer.

For phase modification of the surface layer, the initial sample (sample I) was oxidized at 150 °C in air for 4 hours (to give sample II). From experimental spectra (see Figure 10) it can be concluded qualitatively that in the top layers iron is oxidized and is characterized by different spectra with and without magnetic splitting. The sample II spectra in the right column of Figure 10 clearly illustrate the phase transformation on the top of the α -Fe film. The spectra differ mostly at the lower grazing angles, where the penetration depth is minimal. For example, the contribution of the doublet is much larger for the spectrum of sample II at $\theta = 2.2$ mrad.

Thus even qualitative analysis clearly shows that the technique is more sensitive to the changes of chemical and magnetic states of ultra-thin surface layers than the

Figure 9 Resonant absorption spectrum of ^{57}Fe (295 K) in lunar soil from the Apollo 11 landing site at Mare Tranquillitatis. The absorption in the range between 0 and 0.3 mm s^{-1} results primarily from iron in silicate glass, pyroxene and olivine; the peaks at lower and higher velocities are due to metallic iron.

Figure 10 Sets of TER-CEM spectra (a) for the initial sample α - ^{57}Fe (enriched up to 90% and $\sim 50\text{ nm}$ thick), sputtered on a 10 mm thick beryllium disk (sample I) and (b) after oxidizing in air for 4 hours at 150 °C (sample II). TER takes place at grazing angle $\theta \sim 3$ mrad.

usual CEMS techniques. Detailed information about distributions of different phases with depth may only be obtained after quantitative analysis of sets of spectra. The results of calculations for the initial sample are given in **Figure 11**. It is seen that the α -Fe phase is present in the top layer also. This points to the existence of an island phase structure of the top layer. The amount of FeOOH phase increases with depth but has a maximum value at ~ 10 nm. From analysis of histograms such as that shown

Figure 11 The histograms of iron content S in different phases of different sublayers (sample I) as function of the lower border of the sublayers. The sample is an iron film about ~ 50 nm thick, sputtered on the beryllium disk of 10 mm thickness. 1, sextet of α -Fe; 2, broadened sextet with smaller magnetic splitting than in α -Fe; 3, asymmetric strongly broadened sextet associated with hyperfine interaction parameters for α -FeOOH; 4, the doublet.

in **Figure 11**, it can be seen explicitly how different oxide phases move inside the sample during oxidation processes.

Industrial Applications

The scope of problems addressed is extremely wide and includes metals research of industrial significance, steel and steel alloys, amorphous alloys and glasses, corrosion, surface magnetism and super-paramagnetism, catalysis and solid-state reactions on solid surfaces, minerals, and mineral processing, superconductivity including high-temperature superconductivity, nanocrystals, thin films, ion implantation and laser treatment of metals, the coal industry, amorphous alloys and glasses, and numerous other miscellaneous applications. Areas of application of Mössbauer spectroscopy to corrosion studies are listed in **Table 4**.

Physical metallurgy is a rather wide field of applications of Mössbauer spectroscopy and it is possible to enumerate only the main topics: phase analysis, order-disorder alloys, surfaces, alloying, interstitial alloys, steel, ferromagnetic alloys, precipitation, diffusion, oxidation, lattice defects, etc. Alloys are well represented by the iron-carbon system, the mechanism of martensite transformation, high-manganese and iron-aluminium alloys, iron-silicon and Fe-Ni-X alloys.

Table 4 Corrosion studies using Mössbauer spectroscopy

Processes studied	Corrosive environments, objectives, applications
Passivation	Solutions and electrode surfaces in solutions at various potentials Properties and structure of passive films in solutions, in gases or in vacuum
Corrosion in water and in aqueous solutions	Distilled water The effect of oxygen The effect of other admixtures in water The temperature effect in aqueous media Water vapour corrosion
Corrosion in gases	Corrosion in power plants Pure oxygen or dry air Atmospheric and water vapour corrosion Aggressive gases Combined action of both gas media and solutions
Corrosion in aggressive environments	Acids Alkalis Organic and natural media Corrosion in tubing and autoclaves Applications in agriculture
Specific corrosion processes	Stress corrosion Corrosion beneath lake and polymeric coatings Transformations of corrosion products to enhance the protective properties and to identify the corrosion products
Inhibition and passivation	The effect of special inhibiting or passivating admixtures on the composition and growth rate of protective films
Corrosion of amorphous alloys	Materials science A check on the theory used to describe corrosion of amorphous alloys
Internal oxidation	Materials science

There have been a number of regional and international conferences devoted to industrial applications of Mössbauer spectroscopy or specific problems of materials science. The scope of problems addressed is extremely wide and ranges over all the above-mentioned problems. One can expect the contributions of Mössbauer spectroscopy in industry to divide into three areas: (1) as a research tool, (2) in quality control, and (3) for in-service evaluation. Unfortunately, there are still very few Mössbauer instruments in use for quality control, or for in-service evaluation of materials or surface. More than 99% of Mössbauer publications cover use of the technique as a research tool.

An example of the application of Mössbauer spectroscopy to metals research of industrial significance is the study of fractures and ruptures in steels (see **Figure 12**). The phase compositions of the metal microvolumes that are the sites for the propagation of fractures were determined. The spectra obtained from the fracture surfaces after various cyclic loadings are a superposition of a sextet with a single line in the centre (γ - and ε -phases). The central line is identical to that of the original sample, the sextet lines being broadened. Such line broadening may be attributed to different local environments of Fe atoms, or to significant local lattice distortions, or to both. It follows from **Table 5** that on increasing the loading rate the surface layer of the fracture is enriched in martensite. The appearance of the

α -phase at the site of destruction and its predominance there explains the contradiction between the intercrystallite character of the steel destruction and the high energy that is required. Martensite in the fracture layer is formed in front of a crack to be nucleated and propagated. The predominance of martensite in the fracture layers testifies to the large number of cracks in this area and to a significant stress relaxation preceding the formation and development of the cracks. This is the reason for the high energy of destruction of steels with the initial ($\gamma + \varepsilon$) structure. A comparison of the CEMS and X-ray detection data shows that the processes responsible for the destruction of steels with the $\gamma + \varepsilon$ structure are localized in a zone with a width less than 5 μm . On static loading tests, the width increases up to 10 μm .

Concluding Remarks

The technique has grown rapidly and is now an effective form of spectroscopy. Mössbauer spectroscopy using ^{57}Fe is so simple and straightforward that it is now an integral part of many undergraduate laboratory curricula.

An explosive growth in the application of Mössbauer spectroscopy in a broad range of scientific areas has resulted in publications in a diverse number of journals. From January 1978, the Mössbauer Data Center in Virginia, USA has published the *Mössbauer Effect Reference*

Figure 12 (a) An 8 mm fracture of steel with the initial $\gamma + \varepsilon$ structure (19.2% Mn, 1.67% Si, 0.9% Ti, 0.07% C). (b) CEMS spectrum of the steel from the fracture surface shown in (a). (c) CEMS spectrum after annealing at 1050 °C for 6 hours, followed by cooling in air.

Table 5 Results of the phase analysis of iron-based alloy (19.2% Mn, 1.67% Si, 0.9% Ti, 0.07% C)

Loading	Detected radiation	Parameters of the $\gamma + \epsilon$ phases		Parameters of the magnetic phase			Phase composition (saturation effect and rescattering are accounted for)	
		$\delta_{\gamma + \epsilon}$	$\eta_{\gamma + \epsilon}$	$\langle H_{\text{eff}} \rangle$	δ_{α}	H_{α}	$C_{\gamma + \epsilon}$	C_{α}
Low-cycle fatigue	Electrons	− 0.12	28	27.3	− 0.01	72	27.6	72.3
	X-rays	− 0.14	29	27.5	− 0.04	71	35	65
Fatigue tests at 600 cycles min^{-1}	Electrons	− 0.12	10	27.5	− 0.01	90	8.8	91.2
	X-rays	− 0.14	26	27.5	− 0.01	74	31.9	68.1
Impact tests	Electrons	− 0.12	23	28.0	− 0.01	77	21.4	78.6
	X-rays	− 0.15	46	28.1	− 0.05	54	53.2	46.8

$\langle H_{\text{eff}} \rangle$ is the average effective magnetic field at a ^{57}Fe nucleus in the α -phase; $\Delta\delta = \pm 0.01 \text{ mm s}^{-1}$; η_i are the relative areas (%) under the spectrum ($i = \alpha, \gamma + \epsilon$); C_i is the relative content of the i th phase (%), $\Delta\eta = \pm 5\%$, $C_{\alpha} = \eta_{\alpha}/(\eta_{\alpha} + 1.43 \eta_{\gamma})$. H_{eff} values are given in tesla, isomer shifts are in mm s^{-1} .

Symbols

A	hyperfine coupling constant
c	velocity of light
E	energy
E'	energy of interaction of a nucleus with an electromagnetic field
E_0	energy of an excited state
E_0	electric field strength at the centre of the nucleus
E^0	transition energy for $\overline{r^2}$
E_a	transition energy in absorber
E_M^m	shift of levels due to magnetic interactions
E_Q^m	eigenvalues of the H_Q^m Hamiltonian
E_R	recoil energy
E_s	transition energy in the source
$\delta E_{g,e}$	value of the shift of a nuclear level
e	electron charge
e	excited state (index)
$G(m_e, m_g)$	Clebsh–Gordan coefficient
g	ground state (index)
g_I	gyromagnetic ratio
$f(f')$	probability of recoilless emission (absorption), Lamb–Mössbauer factor
$F_L^M(\theta, \varphi)$	angular functions
H	magnetic field strength
H_0	magnetic field strength at the centre of the nucleus
H_{eff}	effective magnetic field acting on the nucleus
H_n	hyperfine field
H	Hamiltonian
H_M	Hamiltonian for interaction with the magnetic field
H_Q	Hamiltonian for interaction with electrons
H_Q^m	Hamiltonian
H_δ	Hamiltonian
H'_{mm}	matrix element of the Hamiltonian H
I	nuclear spin
I	nuclear spin operator

$J_R(E), J_M(E)$	energy distributions of Mössbauer γ -rays
k_B	Boltzmann constant
k	wave vector
$L(E)$	Lorentzian line
M	mass of nucleus
$M1$	magnetic dipole transition
m	spin projection onto the quantization axes
$n = 1 - \sigma - i\beta$	the complex index of refraction
p	vector of electric dipole moment
P	probability of a nuclear transition
Q_{ik}	tensor of the electric quadrupole
qeZ	nuclear charge
R	reflectivity
r_p	radius-vector of the p th proton
$\overline{r^2}$	mean-square radius
S	electronic spin
T	temperature
v	velocity
$\overline{x^2}$	mean square displacement of the Mössbauer atom
Z	number of protons in the nucleus
Γ	full width at half-maximum
Γ_{nat}	natural line width
γ	glancing angle
γ_{cr}	angle of total reflection (the critical angle)
γ_∞	antishielding factor
Δ	quadrupole splitting
δ	isomer (chemical) shift
ε	resonance effect magnitude
δ'_{mm}	Kronecker symbol
$\eta = (\varphi_{xx} - \varphi_{yy})/$	asymmetry parameter
φ_{zz}	
Θ	Debye temperature
θ	polar angle, specifying H_{eff}
μ_n	nuclear magneton
μ	vector of magnetic dipole moment
ρ_e	charge density at the centre of the nucleus

τ	lifetime of nuclear excited state
φ	electrostatic potential
φ	azimuthal angle, specifying $\mathbf{H}_{\text{eff}}$
φ_m	wavefunction
$\varphi(r_p)$	electric potential in the vicinity of the p th proton
$\varphi_p(0)$	electric potential at the centre of nucleus due to the p th proton
$\varphi_{xx,yy,zz}$	x,y,z -component of the EFG tensor
$ \psi(0) _{a,s}^2$	the electron density at the nucleus in the absorber (a) or in the source (s)

Mössbauer spectroscopy is concerned with the scattering and emission of γ -radiation by atomic nuclei in the condensed phase. The phenomenon was discovered in 1958 by the German physicist R. L. Mössbauer. It makes use of the probability that the state of a system will remain unchanged when γ -quanta are absorbed or emitted with an energy that is exactly equal to the nuclear transition energy E_0 .

Hence the γ -spectrum $J(E)$ of a Mössbauer source may be represented by the sum of a line $J_R(E)$ that is displaced due to recoil effects and broadened by the Doppler effect, and a line $J_M(E)$ with its centre at the energy that is exactly equal to the transition energy, the half-width being close to the natural one, Γ_{nat} . The $J_M(E)$ part of the spectrum is of particular interest and reveals itself most strikingly when the source and the sample under study

(absorber) are in the solid state, see **Figure 1**. The following normalization conditions may be assumed:

$$\int_{-\infty}^{\infty} J_R(E) dE = 1 - f; \quad \int_{-\infty}^{\infty} J_M(E) dE = f \quad [1]$$

A fraction $(1 - f)$ of the disintegrations occurs with the energy transferred to the lattice, and the fraction f is recoilless.

The particular dependence $J_R(E)$ is of no interest but it should be noted that the centre of gravity of this distribution is shifted by the amount E_R relative to the transition energy E_s in the source. $E_R = E_0^2/2Mc^2$ is the recoil energy imparted to an isolated nucleus of mass M (where c = vacuum speed of light). The energy distribution of the Mössbauer γ -quanta $J_M(E)$ may be considered as Lorentzian $L(E)$ with the full half-width γ such that $\Gamma = \Gamma_{\text{nat}}$. Owing to the normalization conditions, $J_M(E)$ may be written as

$$J_M(E) = \frac{f\Gamma_{\text{nat}}}{2} \frac{1}{(E - E_s)^2 + (\Gamma_{\text{nat}}/2)^2} = \frac{2f}{\pi\Gamma_{\text{nat}}} L(E) \quad [2]$$

The theoretical spectrum of the 129 keV γ -ray of ^{191}Ir absorbed by an atom in iridium metal is shown in **Figure 1**. The Mössbauer spectrometer is sensitive only to the narrow, recoil-free line at zero energy shift, which contains 5.7% of the total area under the curve at 4 K for ^{191}Ir , $E_0 \approx 129$ keV.

There are two types of Mössbauer spectroscopic experiments based on scattering and transmission techniques.

Figure 1 Absorption cross section for ^{129}Ir at 4 K and 300 K. The Debye model was used to calculate the lattice vibration.

Figure 2 Mössbauer periodic table.

In transmission mode experiments, the resonant scattering leads to the sharp attenuation of the radiation intensity registered by a detector; it is therefore sometimes referred to as resonant absorption. The resonant absorption cross section is the total cross section of resonant scattering; the probability of detecting the scattered radiation in transmission spectroscopy may be neglected when the geometrical arrangement is appropriate. Scattering Mössbauer experiments involve the detection of either resonantly scattered γ -quanta or other radiation that is emitted in the process of resonant scattering or immediately after it.

The emission probability f and the absorption probability f' of recoilless γ -quanta and the temperature dependence of f and f' are determined by the γ -quantum energy, the mass of the nucleus, lattice vibrations and other properties of the sample. This is why the Mössbauer effect is not observed for all elements (see Figure 2).

The Mössbauer Effect Probability

To obtain information on chemical bonds of atoms in solids from experimental data, an explicit theoretical relation is needed to associate experimental f (or f') values with the phonon spectrum and the force constants of the crystal. Unfortunately, this seemingly rather simple approach produces a number of problems that primarily result from the limited information that is available on the phonon spectra of solids of practical interest. Only for a cubic crystal where interatomic forces may be assumed to be harmonic is there a simple relation for the probability

of γ -quantum resonant emission with a wave vector k when a nucleus undergoes a transition from an excited state to the ground state:

$$f = \exp\{-k^2 \overline{x^2}\}$$

where $\overline{x^2}$ is the mean square displacement of the Mössbauer atom from its equilibrium position at temperature T .

The Debye model is most widely used and is assumed irrespective of the lattice symmetry and the number of atoms in the unit cell. Hence, from an observed f value the effective characteristic temperature (Debye temperature) Θ may be evaluated and compared with the temperatures obtained for the substance by methods such as X-ray analysis or specific heat measurements. For very low and high temperatures (as compared with Θ),

$$\begin{aligned} f &= \exp\left(-\frac{3E_R}{2k_B\Theta}\right) \quad \text{for } T \ll \Theta \\ f &= \exp\left(-\frac{6E_R T}{k_B\Theta^2}\right) \quad \text{for } T > \Theta \end{aligned} \quad [3]$$

where k_B is the Boltzmann constant. Using resonance atoms as admixtures in various compounds extends the number of solids in which the Mössbauer effect is observable and this expands the usefulness of the method. Unfortunately, the theoretical treatment is much more complicated than that of the ordinary Mössbauer effect.

In general one needs to take into account the dependence of phonon excitation on the direction of the recoil momentum of the nucleus with respect to the

crystallographic axes. This must be considered in particular when strong anisotropy is observed for laminar crystals. The anisotropy factor f' that is detected for some nontextured polycrystalline samples takes this into account in a phenomenon known as the Goldanskii–Karyagin effect.

Hyperfine Interactions and Line Positions in Mössbauer Spectra

The energy of a nucleus, as well as of any system of charges and currents, changes upon interaction with an external electromagnetic field by an amount E' . Using classic electrodynamics, the energy may be described by the multipole moments series as

$$E' = q\varphi_0 - \mathbf{p}\mathbf{E}_0 - \mathbf{\mu}\mathbf{H}_0 - \frac{1}{6} \sum_{i,k=1}^3 \mathbf{Q}_{ik} (\partial^2 \varphi / \partial x_i \partial x_k)_0 - \dots \quad [4]$$

where E and H are the electric and magnetic field strengths, respectively, φ is the electrostatic potential, $q = eZ$ is the nuclear charge, $\mathbf{p}$, $\mathbf{\mu}$ are vectors of electric and magnetic dipole moments, $\mathbf{Q}_{ik}$ is the tensor of the electric quadrupole moment. The subscript zero indicates that the quantity is that at the centre of the nucleus. Moments of higher orders may be neglected. Since nuclei do not have electric dipole moments, the second term of eqn [4] is zero and the energy of a nucleus in an external electromagnetic field is determined by the product of the nuclear (q , $\mathbf{\mu}$, $\mathbf{Q}_{ik}$) and electron (φ_0 , $\mathbf{H}_0$, $(\partial^2 \varphi / \partial x_i \partial x_k)$) factors. In solid-state physics and in fields of application the first factors are supposed to be known.

As seen from eqn [4], the Hamiltonian H , describing the interaction of a nucleus with effective fields, may be represented as a sum of the two Hamiltonians, one for interactions of the nucleus with electrons (H_Q) and the other for interactions with the magnetic field (H_M):

$$H = H_Q + H_M \quad [5]$$

The Hamiltonian of the electrostatic interaction is

$$H_Q = e \sum_{p=1}^Z \varphi(\mathbf{r}_p) \quad [6]$$

where $\mathbf{r}_p$ is the radius vector of the p th proton, $\varphi(\mathbf{r}_p)$ is the electric potential in the vicinity of the p th proton, and the summation is over all protons, $p = 1, \dots, Z$. The coordinate system is chosen such that the origin is at the centre of the nucleus and the axes x^i ($i = 1, 2, 3$; $x^1 \equiv x$; $x^2 \equiv y$; $x^3 \equiv z$) are directed along the principal axes of the tensor of the electric field gradient (EFG) acting on the nucleus. $\varphi_p(0)$ is the electric potential at the centre of the nucleus due to the p th proton and $r_p^2 = \sum_{i=1}^3 (x_p^i)^2$.

Using the fact that the electrostatic potential φ satisfies the Poisson equation $\nabla^2 \varphi = 4\pi\rho_e$, where $\rho_e = -e|\psi(0)|^2$ is the charge density at the nucleus ($r=0$), and introducing the tensor of nuclear quadrupole moment $\mathbf{Q}_{ik}$ and the EFG tensor φ_{ik} , we can now rewrite the interaction of the nucleus with the electric fields as a sum of two interactions

$$H_Q = H_\delta + H'_Q = -\frac{2\pi}{3} e^2 \sum_{p=1}^Z r_p^2 |\psi(0)|^2 + \frac{e}{6} \sum_{i,k=1}^3 \varphi_{ik} Q_{ik} \quad [7]$$

The nucleus is here considered to be a sphere with a mean-square radius $\overline{r^2} = \sum_{p=1}^Z \overline{r_p^2} / Z$ for the ground state (g) and excited state (e). As a rule, $\overline{r_g^2} \neq \overline{r_e^2}$ and the nuclear charge is uniformly distributed inside the sphere. The external electric field acting on such a spherical nucleus does not split the levels but shifts them by the quantity

$$\delta E_{g,e} = \frac{2\pi}{3} e^2 Z \overline{r_{g,e}^2} |\psi(0)|^2 \quad [8]$$

The shift due to Coulomb interactions is of the order of 10^{-12} of the transition energy. The value of the shift for every nuclear level depends on the chemical state of the atom. This is characterized by the $|\psi(0)|_{as}^2$ parameter which is the electron density at the nucleus in the absorber (a) or in the source (s). In a Mössbauer spectrum this part of the full electrostatic interaction manifests itself as the isomer (chemical) shift δ between the centre of gravity of the emission spectrum of the source and the centre of gravity of the absorption spectrum of the sample, which is called the absorber (**Figure 3a and b**). Thus the transition energy in the source E_s is different from the energy E_a in the absorber, both of them being different from the transition energy E^0 for $\overline{r^2} = 0$. It must be appreciated that in Mössbauer experiments it is not the absolute energy of the γ -quanta that is determined but the energy shift of the nuclear levels. The energy scanning is carried out by the use of the Doppler effect. Therefore, the energy parameters (Γ , δ) are expressed in velocity units, u . For a pair of source and absorbed nuclei we may write

$$\delta = \frac{2\pi}{3} Z e^2 (\overline{r_e^2} - \overline{r_g^2}) (|\psi(0)|_a^2 - |\psi(0)|_s^2) \quad [9]$$

The charge density at the nucleus is mainly determined by s electrons and only partially by p electrons. The main effect of the p electrons and d electrons and any other electron shells that do not contribute directly to the electron density $|\psi(0)|^2$ is to shield the s electrons. The determination of the scale factor $(\overline{r_e^2} - \overline{r_g^2})$ in eqn [9] is called the isomer shift calibration. The interpretation of isomer shifts in Mössbauer spectra involves the correlation of a given $\Delta\rho_e(0) = |\psi(0)|_a^2 - |\psi(0)|_s^2$ value (the electron density difference) with the known electronic

Figure 3 (a) Energy level shifts for a ^{57}Fe nucleus, resulting in the appearance of the isomer shift δ . (b) The corresponding Mössbauer spectrum.

structure of the Mössbauer atom or the change of the structure resulting from the examination of different samples. It should be noted that only one part in 10^{20} of the electrons in a solid directly participate in the isomer shift; the nuclear parameter $(r_e^2 - r_g^2)$ is of the order of 10^{-29} cm^2 . The isomer shift is four orders of magnitude smaller than the Lamb shift caused by quantization of the electromagnetic field.

The second of the above-mentioned interactions is known as the electric quadrupole interaction, H'_Q . The value of Q_{zz} when the nucleus is in the state $m=I$ is conventionally called the nuclear quadrupole moment $eQ = \langle I, I | Q_{zz} | I, I \rangle$. The EFG tensor in the principal axes, taking into account Laplace's equation, is determined by two independent parameters: first, φ_{zz} , commonly called 'the electric field gradient' or 'the principal component of the electric field gradient tensor' and sometimes written as $\varphi_{zz} = eq$; second $\eta = (\varphi_{xx} - \varphi_{yy}) / \varphi_{zz}$, called the 'asymmetry parameter', the axes being chosen such that $|\varphi_{zz}| > |\varphi_{xx}| > |\varphi_{yy}|$ with $0 < \eta < 1$.

In Mössbauer spectroscopy it is necessary to evaluate the eigenvalues of the H'_Q Hamiltonian, that is the energies E_Q^m for the ground state and for the excited state, the transition from which is followed by the emission of a Mössbauer γ -quantum (see **Figure 4a**). The line positions in Mössbauer spectra are determined by the eigenvalues of the sum Hamiltonian H_Q for the nucleus in excited and ground states in the source and absorber, i.e. both δ value and E_Q^m . The intensities of the lines that provide valuable information on the structure of the surface layers are determined by the eigenvectors of the Hamiltonian H'_Q .

Figure 4 (a) The splitting of the excited level of a ^{57}Fe nucleus due to the electric quadrupole interaction Δ . (b) The corresponding Mössbauer spectrum.

For the axially symmetric EFG tensor ($\eta=0$) the degeneracy of the nuclear energy levels is not completely split, and the energy depends only on the absolute value of the spin projection. The energy level displacement is given by the expression

$$E_Q^m = \frac{e\varphi_{zz}Q}{4I(2I-1)} [3m^2 - I(I+1)] \quad [10]$$

where m is the value of the spin projection onto the quantization axis. If the nuclear spin is half integral, the quadrupole interaction will cause the levels to be at least twofold degenerate. If the spin values are integral, the level degeneracy for $\eta \neq 0$ may be completely lifted. For $\eta \neq 0$, the E_Q^m values may be found by solving a secular equation that has no general analytical solution for $I > 2$. Of special interest in Mössbauer spectroscopy are the transitions between states with spin quantum numbers $I = \frac{1}{2}$ and $I = \frac{3}{2}$. This is the case for ^{57}Fe , ^{119}Sn , ^{125}Te and many other nuclides. The quadrupole splitting, the distance between two lines, is equal to

$$\Delta = \frac{|e\varphi_{zz}Q|}{2} \left(\frac{1+\eta^2}{3} \right)^{1/2} \quad [11]$$

According to Sternheimer, two primary sources of the EFG may be identified: first, charges on ions surrounding the nucleus (provided the symmetry of the surroundings is lower than cubic), and secondly, the unfilled valence

shells (since filled shells possess a spherically symmetric charge distribution). The actual EFG at the nucleus is determined by the extent to which the electronic structure of the Mössbauer atom is distorted by electrostatic interactions with external charges. This leads to the so-called ‘anti-shielding’ effect, which is described by $1 - \gamma_\infty$.

The Hamiltonian for the interaction of the magnetic dipole moment of a nucleus with the effective magnetic field H_{eff} acting on it may be written

$$E_M = -g_I \mu_n \mathbf{I} H_{\text{eff}} \quad [12]$$

where μ_n is the nuclear magneton, g_I is the gyromagnetic ratio, $\mathbf{I}$ is the nuclear spin operator (the quantization axis coincides here with the direction of H_{eff}). The degeneracy of the nuclear levels is completely split. **Figure 5** depicts the splitting of the nuclear energy levels and the corresponding Mössbauer spectrum. The shift of the levels is determined by the expression

$$E_M^m = -g_I \mu_n m H_{\text{eff}} \quad [13]$$

Figure 5 Effect of the magnetic dipole interaction on energy level splitting in ^{57}Fe . (a) Energy level diagram in the field $H_{\text{eff}} \neq 0$, $\varphi_{zz}=0$. (b) The corresponding Mössbauer spectrum.

(where m = spin projection onto the quantization axis). In ^{57}Fe , where the transition multipolarity of interest is $M1$, $m_e - m_g = 0, \pm 1$, and out of eight possible transitions in H_{eff} only six are present (**Figure 5a** and **5b**).

Often all three interactions, i.e. the electric monopole, magnetic dipole and electric quadrupole interactions, occur simultaneously. If the quadrupole interaction is small compared with the magnetic interaction ($E_Q^m \ll E_M^m$), a correction to the interaction energy may be applied using first-order perturbation theory for a nondegenerate spectrum. For the case of an axially symmetric EFG tensor ($\eta=0$), the level positions are given by

$$E_M^m = -g_I \mu_n m H_{\text{eff}} + \frac{eQ\varphi_{zz}}{4I(2I-1)} [3m^2 - I(I+1)] \frac{3\cos^2\theta - 1}{2} \quad [14]$$

The splitting of the energy levels and the corresponding Mössbauer spectrum are shown in **Figure 6a** and **6b**. If the z axis of the axially symmetric EFG is parallel to the magnetic field $E_Q^m \sim E_M^m$, the hyperfine structure is also described by eqn [14]. The sublevels are not equidistant. This results in an asymmetric magnetically split Mössbauer spectrum as depicted in **Figure 6b**. For the more general case, there is a dependence of the sublevels shift on the angle θ . If $E_Q^m \sim E_M^m$, $\eta=0$ and $\theta \neq 0$, then the wavefunctions φ_m describing a nuclear state with a definite spin projection m onto the z axis are not the

Figure 6 (a) Energy level splitting diagram with combined hyperfine interactions ($E_Q^m \ll E_M^m$) for ^{57}Fe . (b) The corresponding Mössbauer spectrum.

eigenfunctions of that Hamiltonian. The wavefunctions of the nuclear state with energies given by the roots of the secular equation $\text{Det}(H_{mm'} - \epsilon \delta_{mm'}) = 0$ will be a superposition of φ_m functions at different m ($H_{mm'}$ is the matrix element of the Hamiltonian H).

The superposition will cause the relative line intensities of the Mössbauer spectrum to be different from those characterizing a pure magnetic interaction. This effect may also give rise to the appearance of additional lines in the Mössbauer spectrum.

Relative Intensities of Spectral Lines

In the absence of relaxation effects and saturation arising from finite sample thickness, the intensity of a spectral component is determined by the nuclear transition characteristics (see **Figures 3–6**). The most important of these are the spin and the parity of the excited and ground states of the Mössbauer nuclei, the multipolarity of the transition, and the direction of the wave vector $\mathbf{k}$ of the γ -quanta emitted with respect to a chosen direction which is specified, for example, by the magnetic field or by the electric field gradient that causes the nuclear level degeneracy to be lifted.

The probability P of the occurrence of a nuclear transition of multipolarity $M1$ from a state $|I_e m_e\rangle$ to a state $|I_g m_g\rangle$ equals

$$P(I_g m_g 1M, I_e m_e; \theta, \varphi) = |G(m_e, m_g)|^2 F_L^M(\theta, \varphi) |\langle I_g || 1 || I_e \rangle|^2 \quad [15]$$

where θ, φ are the polar and azimuthal angles determining the direction of emitted γ -quanta in the coordinate system defined by the magnetic field direction, $M = m_e - m_g$; $G(m_e, m_g) = \langle I_g m_g 1M | I_e m_e \rangle$ are the Clebsh–Gordan coefficients; $\langle I_g || 1 || I_e \rangle$ is the reduced matrix element which does not depend on the quantum numbers m_g, m_e . The angular function $F_L^M(\theta, \varphi)$ is determined only by the transition multipolarity. The intensity of the Mössbauer line is proportional to the product of the Clebsh–Gordan coefficients and the $F_L^M(\theta, \varphi)$ functions. Plots of angular dependence of the intensities of the spectral components are given in **Figure 7**. In the sample the purely magnetic hyperfine splitting of nuclear levels takes place.

The effect of anisotropy of atomic vibrations in solids not only causes the Mössbauer effect probability f to be anisotropic in single crystals, but may also lead to anisotropy in f for nontextured polycrystalline samples consisting of randomly orientated crystallites. The relative line intensities of the Mössbauer spectrum (**Figures 3–6**) will be different for negative and positive velocities. Similar deviations may be caused by texture, that is by a preferred orientation of crystals in a polycrystalline sample.

Resonance Fluorescence and Interference Effects

The resonantly scattered radiation may interfere with the radiation scattered by electrons of the atom. The characteristic time – the lifetime of nuclear excited state

Figure 7 Angular dependences of relative intensities of the hyperfine structure components for the $I_e = 3/2, I_g = 1/2$ transition in ^{57}Fe , for the magnetic dipole interaction. The polar angle θ , defining the wave vector $\mathbf{k}$ of the emitted γ -quantum, is the angle between the radiation direction and the quantization axis. The quantization axis z is parallel to H_{eff} .

$\tau \propto \gamma^{-1}$ – is longer by several orders of magnitude than the lattice vibration periods. There is no correlation here between the initial and final positions of the atom. Despite this, the scattered wave remains coherent with the incident one.

The energy distribution of the scattered γ -radiation may differ substantially from that of the incident radiation and is determined by convolution of the emission and scattering spectra. The Rayleigh scattering spectrum intensity effectively coincides with the emission spectrum. The intensity of the resonantly scattered radiation follows the usual Lorentzian curve, while the contribution of the interference term to the total intensity of the scattered radiation takes the form of a dispersion curve. The use of Bragg reflections in a single-crystal scatterer permits a substantial reduction in the contribution from incoherent scattering. The interference pattern in this case may be unambiguously connected with the crystallographic and electronic structure.

The directions of Mössbauer diffraction, when the hyperfine splitting is absent, generally coincide with the directions of Rayleigh coherent scattering. However, the angular dependences of diffraction line intensities from nuclear scattering and Rayleigh scattering are different. Since the Debye–Waller factor decreases with the scattering angle, it is necessary to use large scattering angles to increase the contribution of nuclear diffraction to the total spectrum.

When the hyperfine splitting is present, the diffraction pattern caused by resonant scattering is much more complicated. Magnetic fields at the different Mössbauer atoms may not be parallel. Only one of the spin subsystems will participate in the coherent scattering of the quantum and there will be no cancellation of the scattering amplitudes. This leads also to the observation of pure nuclear diffraction maxima. When the hyperfine interaction energies are sufficiently different, it should be possible to tune the incident radiation to select a particular chemical environment, and then measure the diffraction pattern from only these atoms. Only Mössbauer effect diffraction can provide independent autocorrelation functions for atoms in different chemical environments. Two physical problems must be given special mention. First, the diffraction of Mössbauer radiation is dynamic in nature. Second, the suppression of inelastic scattering channels requires attention. The resulting effect is the nuclear resonant analogue of the Bormann effect and is realized when a thick perfect crystal containing Mössbauer nuclei is set up at a diffraction angle and the transmittance of the crystal increases when the source velocity is such that the system is brought into resonance.

Considerable interest in pure nuclear back-reflections arises also from application to γ -optical devices, such as the filtering of Mössbauer radiation from the white

spectrum of synchrotron radiation. Extremely narrow band with (10^{-6} – 10^{-8} eV) and small angular width (0.4 arc second) have been obtained from the synchrotron radiation continuum. Progress in this technique has made it feasible to produce diffracted γ -quanta with intensities unattainable from conventional Mössbauer sources, thereby increasing interest in hyperfine spectroscopy. The standard experiment is time-resolved observation of forward scattering from a polycrystalline target instead of the pure nuclear reflection from a single crystal that has been used to date. The use of synchrotron radiation allows the Mössbauer effect to be observed in new isotopes. Such isotopes would need low-energy excited nuclear levels but need not have appropriate parent nuclei, and hence they are not given in **Figure 2**. The interference of the elastically scattered radiation gives rise to a mirror-reflected wave. It is known that if electromagnetic radiation falls onto a mirror surface characterized by complex index of refraction $n = 1 - \sigma - i\beta$ at a glancing angle $\gamma \leq \gamma_{cr}$ the reflectivity R , i.e. the ratio of the reflected and incident intensities, becomes equal to unity. For real media there is always some absorption and the imaginary part of the index of refraction is not zero. However, if the R value rises sharply when γ becomes less than γ_{cr} , the situation is described as total external reflection (TER). The coherent amplification of the scattered wave under conditions of TER is analogous to diffraction on scattering from single crystals. The index of refraction depends only on the forward scattering amplitude and hence there is no phase shift between the waves scattered by various atoms and nuclei in the unit cell. In the presence of hyperfine splitting and of non-randomly orientated quantization axes in the scatterer, polarization effects should also be taken into consideration. TER may be used for studies of very thin surface layers.

Relaxation Phenomena in Mössbauer Spectroscopy

The term ‘relaxation’ is used to indicate that time-dependent effects occur in the system under study. The γ -quantum scattering leads, as a rule, only to change of the nuclear state, while the electronic system remains unchanged. Sometimes, i.e. in paramagnets, the interaction of the electronic shell with the environment may be comparable to or much weaker than the hyperfine coupling. The atom follows a random, stochastic ‘path’ through its allowed states owing to time-dependent, extra-atomic interactions, and as a result of the hyperfine interaction the Mössbauer spectrum will be affected.

There are two main types of relaxation in Mössbauer studies: paramagnetic and superparamagnetic relaxation. As a rule, the observed spectra are quite complicated.

The simple relaxation processes for electronic spin $S=1/2$ can be analysed in terms of a fluctuating hyperfine field $H_n(t)$ which takes on the values $+H_n$ and $-H_n$. If off-diagonal terms in the hyperfine Hamiltonian are absent, then

$$H_M = A_z I_z S_z(t) = g_n \mu_n H_n(t) I_z \quad [16]$$

where A is the hyperfine coupling constant and $A_x = A_y = 0$. Under the influence of the electron–bath interaction, the electronic spin $S_z(t)$ fluctuates between the values $S_z = \pm 1/2$ at some rate ν_R . Using either stochastic arguments or a rate equation approach, one can arrive at a closed-form expression for the line shape. The simplicity of the result obtained has made this model very popular. If off-diagonal terms are present in H_M , such simplifications are not possible.

Relaxation theory, as it applies to Mössbauer spectroscopy, has two main approaches: perturbation calculations and stochastic models. The stochastic approach is easily visualized and adapted to various physical situations. The approach generally proceeds by considering the system divided into two parts: the radiating system and the ‘bath’. Depending on the particular model, the bath can induce fluctuations in the radiating system by providing unspecified ‘hits’ or by being represented by a fluctuating effective magnetic field. Blume formulated the effective-field, nonadiabatic model in a particularly useful way by introducing the superoperator (or Liouville operator) formalism. The superoperator formalism is extended to the case where the nucleus, and the atomic electrons are treated as a fully quantum-mechanically coupled system. It is possible to carry out good calculations of all experimental relaxation spectra.

Non-invasive MRI is at the forefront of clinical diagnostic imaging; its non-destructive nature also gives it great potential as a tool in biological research, involving animal models of disease. Because it is possible to scan the same animal as often, and over as long a period, as necessary, before and after experimental surgery and/or administration of test compounds, MRI has a role in longitudinal evaluation of novel pharmaceuticals and characterization of animal models of disease. Experiments can usually be designed so that each subject acts as its own control, increasing statistical power with smaller group sizes, and longitudinal studies are possible without killing groups of animals at each time point; two factors that, separately and in combination, offer dramatic sparing of laboratory animals. In general, measurement of anatomical features from MR images is much quicker than conventional invasive methodologies like tissue histology. It is often possible to acquire MRI data as three-dimensional images with isotropic resolution. These can be subsequently 'sliced' or rendered along arbitrary planes or surfaces to highlight irregular structures. The MR image is acquired *in situ*, so anatomy is undistorted by fixation, excision, sectioning and staining processes. Finally MRI methods developed to highlight

features of animal disease models are often directly transferable to clinical trials and diagnoses.

MRI is so powerful because of the wide range of contrast mechanisms available to differentiate different organs, tissues and pathologies. The physicochemical basis of these contrast mechanisms and the MR pulse sequences designed to exploit them are treated in comprehensive standard works and other articles in this Encyclopedia. Important sources of MRI contrast are described below.

Differences in tissue water T_1 and T_2 relaxation times generally depend on differences in the extent to which water molecules interact with soluble macromolecules. Thus changes in the concentration of soluble proteins in oedema will usually cause changes in T_1 and T_2 , so that MRI acquisition sequences weighted according to one (T1W or T2W) or both of these will distinguish oedematous from normal tissue. Water–macromolecule interactions are also the basis of magnetization transfer contrast (MTC), particularly effective at highlighting fibrous structures like cartilage. 'Pools' of water in which diffusion is more or less restricted by cell boundaries, or anisotropic environments, can be distinguished by diffusion weighted (DW) imaging. DWI is particularly effective at detecting cell swelling during ischaemic energy depletion, and in delineating the course of highly anisotropic microstructures like nerve cells. MR pulse sequences, which refocus magnetization using pulsed magnetic field gradients rather than spin echoes, produce images which are sensitive to differences in magnetic susceptibility between and within tissue, and are a function of the 'inhomogeneous' T_2' , or T_2^* . Because paramagnetic deoxyhaemoglobin and diamagnetic oxyhaemoglobin affect the magnetic susceptibility of neighbouring tissues in very different ways, T_2^* weighted (T2*W) techniques can be used to define tissues where deoxyhaemoglobin has built up as a result of underperfusion, or where metabolic activation has increased oxygenated blood – Blood Oxygen Level Determination (BOLD). MR angiography (MRA) takes advantage of the different behaviours of moving and static nuclear spins, and can delineate vasculature and measure blood flow. Tissue perfusion can be measured using paramagnetic contrast reagents, usually stable chelates of gadolinium or manganese ions, or preparations of magnetic iron oxide particles, which reduce tissue relaxation times. T1W,

T2W or T2*W images are obtained before and after administration (usually intravenously) of a contrast reagent; regions accessible to the reagent change in MRI intensity, and the time course of 'wash in' and 'wash out' gives a measure of perfusion status. Contrast reagents are widely used in animal models where the blood–brain barrier is compromised (such as demyelinating disorders and stroke), in studies of tumour perfusion, and as an alternative or adjunct to MRA.

Practicalities

Although useful work is possible in vertical magnets designed for high resolution spectroscopy, most animal MRI is done in horizontal superconducting magnets with field strengths ranging from 2 to 7 T (corresponding to ^1H resonances from 86 to 300 MHz) and clear magnet bore diameters ranging from about 20 to 40 cm. Concentric shim, gradient and RF coils reduce the useable diameter of 20 and 40 cm systems to about 8 to 20 cm respectively. Subjects must usually be anaesthetized with a suitable inhalation (e.g. isoflurane, halothane) or injectable (e.g. alphaxalone/alphadalone, fentanyl/fluanisone and midazolam) anaesthetic compatible with the animal model under study. It is often necessary to coordinate, or 'gate', the acquisition of NMR data with heart beat and breathing, which can be done by monitoring the animal's electrocardiogram (ECG) and respiration, and triggering data acquisition in synchrony with one or both. Tracheal intubation and mechanical ventilation allow respiratory gating on the ventilation cycle. Whether triggering is necessary or not, ECG and respiratory monitoring are essential for ensuring animal well-being and effective anaesthesia in the magnet. Other vital parameters like rectal temperature and blood pressure are often also monitored, and animal temperature can be controlled with thermostatted heating blankets or air conditioning. Radio frequency probe and animal holder design is the province of the on-site engineer in many institutions, but increasingly manufacturers are offering these items ready made. At the conclusion of an experiment it is still usual to compare *in vivo* MRI measurements with more conventional histological or organ weight measurements. **Figure 1** shows an unconscious rat supported in an animal holder and connected to ECG and respiratory monitoring systems (lower), and about to be inserted into a typical horizontal laboratory MR scanner (upper).

Applications

Central Nervous System

MRI has been fruitfully applied to a number of animal models of CNS conditions, such as demyelination (as in for instance experimental allergic encephalomyelitis,

EAE), excitotoxicity and neurotoxicity, identification of the spread of neuronal depolarization in the cortical spreading depression phenomenon, identification of neuroanatomical abnormalities in genetically modified animals, blood–brain barrier disruption using contrast reagents and localization of sites of action of psychoactive compounds using BOLD.

The versatility of MRI in this area is well illustrated by its application in models of stroke, where it has been widely used to study the evolution and properties of lesions produced by experimental cerebral ischaemia. Models investigated by MRI include permanent and transient versions of carotid artery, four vessel and middle cerebral artery occlusion (the latter commonly known as MCAO), in rats, mice, gerbils and larger animals like cats. The clarity of T2W images of ischaemic infarcts in some of these models makes this area extremely attractive for the development and implementation of 'high throughput' MRI screening strategies in testing neuroprotective treatments. MRI can exploit different sources of contrast to define the physiological events underlying ischemic injury. Thus **Figure 2** shows representative MR image slices through the brains of rats during an experiment to study the efficacy of an experimental neuroprotective treatment. The top row images are from a control subject, and the bottom row from a subject that received a neuroprotective treatment. Columns labelled (A) and (B) were acquired during a 100 minute period of MCAO using T2*W and DW respectively. In the ischaemic hemisphere (right hand side of each transverse brain image) buildup of paramagnetic deoxyhaemoglobin causes ischaemic regions with perfusion deficit to darken on the T2*W images due to T2* shortening. Additionally, cells swell and undergo cytoskeletal changes in response to energy depletion, which restricts the diffusion of tissue water. These regions show up bright relative to non-ischaemic tissue in DW imaging. Diffusibility changes are further emphasised if DW images are acquired using several different diffusion encoding gradient strengths, allowing a diffusion coefficient to be calculated for each pixel in the image, and the spatial dependence of the diffusion coefficient itself is displayed as a 'map' (column C). In contrast to DW and T2*W images, during and shortly after ischaemia no lesion is apparent using T2WI. However, 24 h after the transient MCAO oedema in the infarcted region manifests clearly as hyperintensity using T2W imaging; columns (D) and (E) show transverse and horizontal slices respectively through the same 3D T2W datasets at this time point. Apart from the distribution of oedema, which can be easily quantified, the high isotropic ($\sim 140\ \mu\text{m}$) resolution facilitates observation of a number of other neuro-anatomical structures, such as the fluid-filled ventricles. Concerted application of different MRI J;acquisition modalities enables one to measure areas undergoing energy depletion, perfusion deficit and

Figure 1 Lower: Unconscious laboratory rat mounted in a non-magnetic holder for MR scanning. Note the face mask for delivery of inhalation anesthetic, conducting sticky pad electrodes on fore and hind paws for ECG signal detection, and the lever (containing a fibre optic cable) placed over the abdomen for respiratory monitoring. Incisor and ear bars are also built into the assembly for stereotaxic positioning if necessary. Upper: The entire animal holder about to be inserted into a 7 T laboratory scanner. Although the notional diameter of the horizontal superconducting magnet is 18.3 cm the addition of concentric shim, pulsed field gradient and resonator coils reduces the useable diameter to about 7 cm – adequate for most small laboratory rodents. The gradient coils produce linear variations in the magnetic field of up to 150 mT m^{-1} (15 gauss/cm^{-1}) in each of three orthogonal directions; they are actively shielded to reduce induction of eddy currents in the magnet bore. ECG (electric) and respiratory (optical) signals are sent to monitors and triggering electronics outside the RF-impenetrable Faraday cage containing the magnet.

oedema, and make inferences regarding areas at risk at early time points which are destined to evolve into infarcts, and those which may be salvageable by neuro-protective intervention.

The strong directionality of nerve fibres makes DW imaging a very useful method for delineating neuro-anatomy, and for studying models of neurodegenerative disorders like demyelinating diseases. **Figure 3** shows

Figure 2 300 MHz MR images from the brains of rats subjected to temporary MCAO. The top row of images was acquired from a control animal, and the bottom row from an animal which received a prior neuroprotective treatment. Columns (a)–(d) show transverse images across the brain and column (e) shows a slice taken horizontally. The image columns show: (a) T2*W and (b) DW images acquired during the 100 min period of MCAO; areas of deoxyhaemoglobin buildup, and restricted diffusion, show up as dark and bright regions respectively in the affected (right) cerebral hemisphere; (c) Diffusion map plotting diffusion coefficients during the ischaemic period, calculated from images acquired with three different diffusion gradient strengths; areas of decreased diffusibility which show up bright in (b) manifest lower diffusion coefficients and hence appear dark in the map; Representative transverse (d) and horizontal (e) slices through 3D T2W images acquired 24 h after 100 min MCAO, in which oedema in infarcted regions appears bright. Pulse sequence conditions were: (a) Gradient echo technique, TE/TR = 13/1000 ms, flip angle $\alpha = 90^\circ$; (b) TE/TR = 64/1200 ms, diffusion sensitization applied in vertical direction, b value = 11 370 s cm⁻²; (c) Diffusion coefficient map calculated by exponential fitting the signal intensity decay to 3 b values of 0, 2350 and 11 370 s cm⁻²; (d) and (e) Interecho delay = 6.5 ms, which a repetition (RARE) factor of 16 converts to a TE_{effective} of 54 ms, TR = 1500 ms.

slices through a rodent brain acquired with diffusion sensitization in different directions. Nerve fibres which run parallel to the diffusion gradient direction show up dark (due to relatively unrestricted diffusion along the fibre) while those running orthogonal to the gradient direction manifest as bright because diffusion across the axon is relatively restricted, so signal loss during diffusion sensitization is minimal.

Cardiovascular System

Gating of the MRI acquisition to the cardiac and (preferably) respiratory cycles is essential in studies of cardiovascular anatomy and function. Images acquired at full systole, and diastole, enable one to measure the change in volume of the four chambers of the heart during a single contraction, and so calculate the ejection fraction. By preceding the MRI acquisition sequence with a selective presaturation method like DANTE, parts of the

myocardium can be 'tagged' and their movement during the cardiac cycle mapped and correlated with cardiac dysfunctions.

Cardiac enlargement, or hypertrophy, is common in diseases like congestive heart failure, and can be a drug side effect. MRI is well suited to measuring changes in the cross-sectional area, or volume, of the chambers, and changes in wall thickness in response to hypertrophic stimuli. **Figure 4** shows transverse slices through the chests of three rats, orthogonal to the long axes of their hearts, acquired at diastole when the heart is fully distended. Image (a) is from a control animal, image (b) is from an animal which has received treatment which increases ventricle lumen size, and image (c) is from an animal after administration of an agent to increase wall-thickness, respectively; both effects are quantifiable from the images. The coronal image (d) shows the aorto-venacaval shunt (AVS) which caused the lumen increase seen in (b); the success of the operation is

Figure 3 Transverse diffusion weighted MR images of a rodent brain acquired at four different levels (images progress from caudal ('back') to rostral ('front') from left to right). Images were acquired with TE/TR=82/2000 ms, field of view (FOV)=2 cm, and diffusion sensitization $b = 0$ (top row), and $b = 29\,600\text{ s cm}^{-2}$ applied in a horizontal direction (2nd row) and orthogonal to the slice direction (3rd row). Further anatomical definition is apparent in difference images (4th row) calculated by digitally subtracting one diffusion sensitized image slice from another. Neuroanatomical structures delineated by the DWI method, and closely corresponding to structures identifiable using different histological stains (5th and 6th rows) are labelled as follows: CCTX – cerebral cortex; THAL – thalamus; HIP – hippocampus; cc – corpus callosum; STR – striatum; HYP – hypothalamus; ox – optic chiasm; ec – external capsule; 3v – third ventricle; LV – left ventricle; ot – optic tract; vsc – ventral spinocerebellar tract; ac – anterior commissure; cg – cingulum.

obvious from the distension of the descending aorta and inferior vena cava in this bright blood image. Without MRI the success of the AVS could only be confirmed *post mortem*.

Detection of atherosclerotic plaque would be extremely useful in evaluating therapy to reduce deposition in blood vessels. Atherosclerosis models usually involve feeding appropriate animals diets rich in fat and

Figure 4 Transverse 300 MHz gradient echo (TE/TR = 4/1000 ms, flip angle = 90°) images through the chests of (a) a control rat, and (b) and (c), animals subjected to experimental treatments which increase the heart ventricular lumen size, and wall thickness, respectively; image acquisition was triggered on the QRS complex of the ECG signal obtain images with the hearts in diastole and hence fully dilated. Panel (d), a coronal 'bright blood' image obtained from the same animal shown in (b), depicts the enlargement of the great vessels in the abdomen provoked by an aorto-caval shunt operation.

cholesterol to induce plaque; this process may take many months so that conventional longitudinal studies use large groups of animals killed at a number of time points. Plaque detection by MRI obviates this need for large multi-group studies. **Figure 5** shows slices from 3D T2W datasets acquired around peak cardiac systole, in a transgenic atherosclerosis-prone mouse, from the region above the heart containing the aortic arch and branch points of the vessels supplying the upper body, shown in the coronal slice (a). Panel (b) is a transverse slice through the branching vessels before induction of atherosclerosis, while (c) and (d) were obtained after a few months on a high fat diet. Strong flow and turbulence around the aortic arch region make it a primary site for plaque deposition, but cardiac and respiratory motion here make good image acquisition challenging. Nevertheless the buildup of atherosclerotic plaque is clearly visible and quantifiable in, for instance, the innominate artery.

MR angiography (MRA) can be used to define vascular anatomy. **Figure 6** shows 3D images from the brain, and the upper abdomen, of a rat acquired with a fast gradient echo technique. Static water in the field of view undergoes saturation on account of the high pulse repetition rate, but blood flowing into the field of view during acquisition gives a strong signal. The delineation of the portal vasculature achieved by this technique is

further enhanced by administration of a suitable contrast reagent; the cerebral vasculature is well delineated without any enhancing agent.

Liver

As the site of metabolism and toxicity of many xenobiotic compounds, non-invasive characterization of liver properties is of great interest. Many physiological and pharmacological interventions change liver size and morphology but its irregular shape can make quantification difficult; the use of pulse sequences giving adequate contrast between liver and surrounding tissues is essential. **Figure 7** shows a series of coronal slices from a 3D image from a rat abdomen acquired with a T1W method. Such data allows accurate liver volume quantification and measurement of changes induced by natural diurnal variations and feeding, and hypertrophic stimuli. Many stresses also cause changes in liver ultra-structure; although *in vivo* MRI cannot resolve microscopic necroses, these often manifest in changes in the gross MRI properties of the tissue reflected in changes in relaxation or diffusion contrast, or altered susceptibility to contrast reagents. Note the excellent delineation of other abdominal organs, particularly the stomach, kidneys and adrenals, and the abdominal aorta.

Figure 5 Coronal (a) and transverse (b)–(d) image slices through the aortic arch region of an atherosclerosis-prone mouse acquired before (a) and (b) and 17 weeks after (c) and (d) commencement of a high fat diet, selected from 300 MHz 3D T2W datasets. Plaque is arrowed in (c) and (d); perivascular fat is removed from the latter by a fat suppression procedure. In these spin echo ($TE/TR = 13/1000$ ms) images triggered in full systole 65 ms after the QRS wave, rapidly moving blood gives no NMR signal and so appears black.

Figure 6 'Stereo pairs' of 'maximum intensity projection' bright blood MR angiograms acquired from rat brain (a) and abdomen (b). Contrast between flowing and static fluid was enhanced in (b) by administration of a colloidal magnetite contrast reagent which shortens T_2 and T_2^* of blood relative to static tissue. The 3D effect can be best appreciated by viewing the images through stereo viewing glasses.

Figure 7 Contiguous coronal sagittal slices through a 3D dataset (300 MHz) acquired from the upper abdominal area of the rat. The acquisition method, combining inversion recovery (950 ms) and segmented (16, TE = 3.3 ms) low flip angle ($\sim 30^\circ$) fast gradient echo readout, was designed to optimize contrast between liver and surrounding structures, but note also the excellent definition of the kidneys, stomach, and moving (bright) blood in the descending aorta. Abdominal fat was suppressed by selective saturation at 3.25 parts per million (975 Hz) upfield of the water signal before readout.

Kidney

Because it receives such a high proportion of the cardiac output, this organ is another important site of toxicity. T2W and proton density images delineate its anatomically and functionally distinct zones. **Figure 8** shows a slice along the median plane of a T2W 3D image of the kidney of a

healthy rat. The divisions of the organ into outer and inner cortex, medulla and papilla, are obvious, as are neighbouring structures like the adrenal gland and fat pads. Treatment of the animal with regiospecific nephrotoxins produces characteristic changes in the MR images. Thus an inner cortical toxin brightens the corticomedullary boundary due to anomalous water buildup in this region.

Figure 8 Slices through the median planes of 3D 300 MHz T2W images ($TE = 6.5$ ms, $TR = 1.5$ s, multiecho segmentation, or RARE, factor = 32, $TE_{\text{effective}} = 104$ ms) of kidneys from a control rat (a), and from rats treated with an inner cortical (b) and papillary (c) toxin. Note the clear differentiation in the control kidney between cortex, medulla and papilla, and also the good definition of perirenal fat and adrenal glands. Note also the evolution of a hyperintense band in the cortical toxin-treated kidney reflecting derangement of renal tubular function and water buildup in this region. The papillary toxin evokes a loss of papillary–medullary contrast. Marked swelling of both treated kidneys is also obvious and easily quantifiable.

Figure 9 (a) MR images from longitudinal assessment of degeneration of the posterior tibio-tarsal joint of a rat, rendered arthritic by intra-venous injection of a *Mycobacterium butyricum* suspension at Day 1 (200 MHz, $TE/TR = 9/2500$ ms, $100 \times 100 \mu\text{m}$ in plane resolution, 1 mm trans-plane resolution). (b) 400 MHz images of excised tibio-tarsal joints from control and adjuvant-arthritic rats, acquired using autosampler technology ($TE/TR = 8/1000$ ms, $70 \times 70 \times 250 \mu\text{m}$ resolution). Reproduced by permission of Dr. Rasesh Kapadia, SB Pharmaceuticals (now GlaxoSmithKline), Upper Merion, PA.

A papillary toxin evokes buildup of water in the inner zones of the organ leading to loss of medullary–papillary contrast, and swelling. Areas of anomalous MRI appearance correlate well with necrotic areas assessed by *post mortem* histology.

Musculoskeletal System

Articular cartilage is readily visible by MRI. **Figure 9a** shows spin echo T2W image slices through the long

dimension of a tibio-tarsal (ankle) joint of a rat subjected to an arthroscopic procedure. Degradation, remodelling, and swelling of the joint as the disease progresses can be clearly seen. **Figure 9b** displays images acquired from joints excised *post mortem* from a control and an arthritic rat; they were acquired on an instrument custom modified to operate with an autosampler – an example of high throughput biological MRI data acquisition.

Figure 10 200 MHz MR images of a transplanted rat GH3 pituitary tumour. The top pair of images (a) and (b) were acquired with a T2*W gradient echo method (TE/TR = 20/80 ms, flip angle 45°) and the bottom pair (c) and (d) with T2W (TE/TR = 20/300 ms). The left hand images were acquired while the animal breathed normal air-anaesthetic gas mixture, while the right hand images were acquired shortly after switching the breathing mixture to carbogen (5% CO₂). Note the striking increase in intensity in the T2*W image as blood flow to the tumour increases due to vasodilation (b). This vasodilation is also reflected in the increase in T2W intensity in blood vessel cross-sections (d). Reproduced by permission of Dr Simon Robinson and Professor John Griffiths, St George's Hospital Medical School, London.

Oncology

MRI is a powerful technique for investigating the progression and properties of experimental tumours, as exemplified in **Figure 10**, which shows slices through a GH3 pituitary tumour implanted in a rat. Distinction of the tumour from surrounding tissue on the basis of relaxation time differences, and measurement of its volume, is straightforward. The left hand images were obtained with gradient (top) and spin echo (bottom) methodologies respectively while the rat breathed a normal air-anaesthetic mixture. The right hand images were obtained after increasing the CO₂ content of the breathing mixture to 5% – a powerful vasodilatory stimulus. Oxygenated haemoglobin increases in the tumour reducing T2* relaxation, producing more signal in the gradient echo T2*W image. This is a dramatic example of the use of BOLD to study functional activation.

Future Developments

BOLD methodologies aided by fast techniques like echo planar imaging (EPI) in high field magnets promise the localization of the sites of action of neuroactive compounds. Cheaper actively shielded magnets will facilitate

the use of MRI in biology, pharmacology and toxicology as the systems become less demanding of laboratory space. Robust acquisition and processing software will remove the routine conduct of biological MRI from the hands of the NMR expert and place it in those of the biologist. Complete automation of *in vivo* experiments is unlikely, but fully automated imaging of fixed tissue is already possible; 3D images of fixed tissue, which can be subjected to a battery of image analysis procedures, will become valuable complements to conventional fixed tissue histology. Image analysis is the rate-limiting step in many experiments. Perfection of automatic image coregistration and segmentation methods should break this logjam. MRI will be increasingly combined with *in vivo* spectroscopy, and other imaging methods like positron emission tomography (PET) to produce simultaneous anatomical, functional, metabolic and drug distributional information. Finally the interface between experimental and clinical MRI will strengthen as clinical trials are planned on the basis of laboratory protocols and *vice-versa*.

α	flip angle

In 1973 both Lauterbur, and Mansfield and Grannell, proposed that a shift in resonance frequency, induced by a spatially varying magnetic field, could be used to encode the spatial location of nuclear magnetic resonance signals. Developments in the late 1970s demonstrated the feasibility of magnetic resonance imaging and led to the construction of clinical instruments, with the first whole-body image published in 1977 by Damadian and colleagues. Initially a range of different imaging techniques were employed, with commercial developments at first using filtered back-projection. While this is the standard method of reconstruction in X-ray computed tomography (CT), the limited homogeneity of early magnets, together with the inherent variations in human magnetic susceptibility, gave rise to considerable image artefacts. These approaches were superseded by spin-warp imaging, introduced by Edelstein and colleagues in 1980, an extension of Kumar and colleagues' Fourier zeugmatography technique. Spin-warp imaging remains the method used for most clinical magnetic resonance imaging. Imaging techniques are discussed in more detail by Morris and Leach as given in the Further reading section.

The ensuing 20 years saw an unprecedented development in the scope and quality of magnetic resonance imaging, compared with the growth of previous medical imaging techniques. Although the advent of CT revolutionized diagnosis by providing high-quality cross-sectional images, its use has generally been limited to the detection and measurement of anatomical abnormality and it provides limited functional information. As CT was well established when MRI was introduced, MRI initially supplied supplementary information, particularly in neurological examinations where the increased soft-tissue contrast of MRI and lack of bony artefacts allowed better

depiction of the brain and spinal cord, together with improved visualization of physiological processes. Hardware has progressively developed, with the introduction of superconducting magnets leading to more stable and homogeneous magnets and allowing the introduction of higher-field magnets of up to 1.5 T to many hospitals. Magnet field strengths now range from 0.2 T, often with open configurations (based on electromagnets or resistive coils), aiding orthopaedic, paediatric and interventional applications, through 0.5 T (superconductive or permanent, with open designs again possible) used for a wide range of applications, to 1.0 T and 1.5 T superconducting designs, and 'short-bore' magnets with flared apertures to increase patient acceptability. High-field magnets are used where signal-to-noise is a principal concern, for angiography, functional MRI (brain activation), cardiology and real-time imaging. At 1.5 T, magnetic resonance spectroscopy is also possible, with many instruments being capable of proton spectroscopy, and some also having facilities for broad-band spectroscopy. Research sites have installed higher-field magnets, with many 3.0 T installations, some at 4.0–4.7 T and more recent installations at 7 T and 8 T. These systems are primarily used for spectroscopy and for brain activation studies.

There has been a range of further developments in hardware. These include shielded gradient coils, facilitating high-speed imaging by reducing eddy currents, and large increases in the strength and switching speed of gradients, allowing clinical implementation of snapshot imaging, echo planar imaging and similar real-time techniques. Circularly polarized and phased-array coils have significantly increased the sensitivity of measurements, with modern systems having a wide range of coils. Automatic shimming techniques have improved fat signal suppression, as well as aiding spectroscopy. Self-shielded magnets have eased the installation requirements for many clinical systems. These improvements have been accompanied by advances in pulse sequence design, versatility and reconstruction speed. Packages for specific clinical specializations are now available, providing pulse sequences and analysis techniques tailored to particular applications, e.g. functional neuroimaging and cardiac packages. In addition, a range of contrast agents with differing pharmaceutical properties have been developed that are leading to new clinical applications.

Anatomical Imaging

Clinical applications of MRI primarily make use of the high soft-tissue contrast, which can be readily manipulated by appropriate choice of pulse sequences, to demonstrate cross-sectional anatomy at any arbitrary orientation. One of the initial motivations for developing clinical MR imaging instruments was the observation that tumours had long T_1 relaxation times. Although this was shown not to provide a unique discriminator for cancer, the different T_1 and T_2 relaxation times, together with other intrinsic properties affecting the MR signal, allow contrast to be changed between tissues by selecting appropriate pulse repetition times and flip angles (T_1 weighting) and echo times (T_2 weighting). This allows abnormal or distorted anatomy to be seen, and aberrant tissues can often be identified by different relaxation properties. T_1 and T_2 relaxation times reflect the environment and ease of movement of water and fat molecules. The greater the water content and the greater the freedom of movement, the longer are T_1 and T_2 . When water is tightly bound, magnetization transfer imaging techniques can be used to interrogate this bound compartment by exploiting the short T_2 and broad line shape. An off-resonance (several kHz) irradiation suppresses the bound component, without directly affecting unbound water. However, the signal of the unbound water is subsequently reduced by exchange with the partially saturated bound component. A difference image reveals the degree of magnetization transfer.

A basic clinical examination will employ both T_1 - and T_2 -weighted multislice imaging sequences, chosen in a particular plane. Typically a set of scout images (very rapid T_1 -weighted images in several orientations) will be acquired to aid the prescription of these images (orientation and number of slices, etc.). A fast spoiled gradient-echo image (e.g. fast low angle single-shot (FLASH)) might be chosen with a 300 ms repetition time (TR), a 12 ms echo time (TE) and a 70° flip angle (α), to provide T_1 weighting. A dual-echo spin-echo sequence with TR = 2 s, TE = 30 ms and 120 ms, and $\alpha = 90^\circ$ would provide, respectively, proton density and T_2 -weighted images. The gradient-echo image is subject to signal loss in areas of magnetic field inhomogeneity, or variations in magnetic susceptibility, for example in the brain adjacent to air-filled sinuses or near sites of previous haemorrhage. The effect can be minimized by selecting a very short TE, or using a T_1 -weighted spin-echo sequence (see **Figure 1**). With these conventional sequences, straightforward anatomical examinations can be performed in most parts of the body that are free from movement. A number of additional gradient-echo sequences are available that exploit the principle of steady-state free precession. FISP (fast imaging with steady state precession) maintains the steady-state signal,

and does not suffer signal loss from flowing blood, providing high signal from long- T_2 fluids, with a signal that does not depend strongly on TR. This is valuable for generating MR myelograms or for angiography. PSIF (a time reversed FISP sequence also called CE-FAST) provides strong T_2 weighting that is a function of TR.

A further basic sequence that is widely used is the inversion recovery sequence, in which the magnetization is initially inverted, and then sampled with a 90° pulse at an inversion time (TI) after the 180° pulse. This can provide a greater range of T_1 -weighted contrast, and has the particular property that it can be used to null signal from a particular tissue on the basis of its T_1 relaxation time, by selecting the TI to sample signal from that tissue as it recovers through zero longitudinal magnetization. A widely used variant of the inversion recovery sequence is the STIR (short τ inversion recovery) sequence, which is used to null the signal from fat, which usually has a bright signal on T_1 -weighted images and can obscure important anatomical detail. Similar sequences can be used to null the cerebrospinal fluid (CSF) signal in spine imaging, allowing the spinal cord to be clearly seen. A further variant is the FLAIR (fluid attenuated IR) sequence, which nulls CSF in the brain, enhancing visualization of brain tissue. Alternative methods are available to obtain fat, or water, images using selective excitation with, for example, binomial pulses, or conventional frequency-selective pulses, or by employing a multiacquisition method sensitive to the phase difference between fat and water (the Dixon method).

While providing excellent images in many parts of the body, acquisition times for these measurements are relatively long, reducing their value in moving tissues. In areas such as the abdomen, affected by respiratory and bowel movement, image quality can be improved by averaging, at the cost of longer measurement times. In the mediastinum, ECG triggering allows high-quality images at appropriate stages of the cardiac cycle to be obtained, despite the vigorous, multidirectional motion. Image quality can be further improved by placing saturation slabs through moving high-signal regions, or by saturating in-flowing blood in adjacent planes. Respiratory gating, and methods of reordering phase encoding (ROPE), can also reduce motion effects. Although these techniques are still sometimes employed, major advances in imaging moving tissues, and in speeding up examinations, have been attained by a range of new rapid imaging techniques, made possible by advances in instrumentation. Where motion cannot be avoided, or where individual data sets building an image have to be acquired during movement, navigator echoes provide a way of accurately monitoring motion as well as providing the information necessary for correcting for the motion.

Figure 1 Transaxial images through the brain of a patient with a haemorrhagic melanoma metastasis. (a) T_1 -weighted spin-echo image (TR = 665 ms, TE = 14 ms, $\alpha = 80^\circ$) showing bright signal in the regions of recent haemorrhage. (b) T_2 -weighted turbo spin-echo image (TR = 4500 ms, effective TE = 90 ms, $\alpha = 90^\circ$) showing bright signal from cerebrospinal fluid and low signal arising from T_2 shortening due to melanin deposits in the tumour. (c) T_2^* -weighted FLASH image (TR = 1604 ms, TE = 35 ms, $\alpha = 30^\circ$) showing increased T_2^* signal loss within the tumour resulting from susceptibility changes due to melanin.

Turbo or magnetization prepared gradient-echo sequences have one or more preparation pulses, followed by a rapid succession of small flip angle pulses to interrogate the longitudinal magnetization, each encoding a different line in k -space, thus building up the image with only one preparation pulse. This sequence, and variants that further reduce the measurement time by reduced k -space sampling, provides rapid images that allow sub-second image acquisition, and a set of slices can be acquired within a breath-hold period. Preparation can include a large flip-angle pulse or an inversion pulse. Contrast and the relative weighting of spatial frequencies can be altered by changing the k -space sampling order. These techniques are often employed in 3D imaging sequences, to allow a 3D data set to be acquired in an acceptable time. A highly effective sequence providing rapid T_2 -weighted measurements is the turbo spin-echo or RARE (rapid acquisition with relaxation enhancement) sequence. In this sequence, multiple echoes are acquired, each sampling a different line of k -space, thus speeding up acquisition of the image. A consequence of the many 180° pulses is a change in contrast in some tissues compared with spin-echo sequences, as well as increased power deposition. Contrast and resolution can also be varied by altering the k -space sampling scheme. Echo planar imaging uses a single-shot sequence to obtain a full image based on a single preparation or read-out pulse. This is one of the fastest imaging methods and places high demands on the gradient and acquisition system. It is now available on commercial systems, and is being applied to functional and physiological measurements, which are particularly sensitive to motion. A number of variants of the above techniques are in use, including GRASE (gradient and spin-echo), combining spin-echo and gradient-echo imaging and fast imaging with BURST RF excitation, which utilizes a sequence of RF pulses to generate images very rapidly.

Bone is not visible on MR images owing to the extremely short T_2 of hydrogen atoms in bone. The presence of bone can usually be inferred from the lack of signal, although estimation of bone volume is complicated by the relative shift in position of fat with respect to bone (the chemical shift artefact). In some areas of the body, signal voids from air spaces can also complicate interpretation. High resolution 3D imaging of joints can show excellent cross-sectional images of trabecular structure. The development of bone interferometry, based on the loss of signal in T_2^* -weighted images from susceptibility effects, has provided a means of measuring changes in trabecular bone mineral mass in diseases such as osteoporosis. T_2^* includes the contribution of local magnetic susceptibility.

MRI is widely used in musculoskeletal and orthopaedic examinations. The use of site-specific surface coils, combined with 3D or narrow slice imaging

sequences, allows the detailed structure of joints to be visualized (see **Figure 2**). Tendons can be seen as regions of low signal, and there is good contrast between cartilage, synovial fluid and the meniscus. Open magnet designs associated with fast imaging techniques facilitate

Figure 2 Sagittal images through the knee of a patient with a ruptured anterior cruciate ligament. (a) A 3D FLASH image (TR = 25 ms, TE = 10 ms, $\alpha = 50^\circ$) providing thin slice images (1.5 mm) showing trabecular bone structure. (b) A turbo spin-echo image (TR = 4500 ms, effective TE = 96 ms, $\alpha = 90^\circ$) showing synovial effusion and oedema (4 mm slice thickness).

kinetic imaging of joints and tissues. Absence of radiation and the ability to freeze motion have also extended the application of MRI to resolving problems in pregnancy and examining the fetus.

Contrast agents are now widely used to enhance the appearance of pathology, separating it from normal tissues based on differential uptake of a labelled pharmaceutical. These agents principally affect T_1 , as they are usually paramagnetic compounds with several unpaired electrons. These cause increased intensity on T_1 -weighted images in areas of high uptake because of the reduced T_1 . They can also be used to affect T_2 using superparamagnetic or very small ferromagnetic particles, causing a loss of signal on T_2 -weighted images. The most commonly used agent is gadolinium, usually chelated to diethylene triamine pentaacetic acid (DTPA) or similar compounds. The agent is injected intravenously and diffuses rapidly into the extracellular space. Its first use was to demonstrate breakdown of the normal blood–brain barrier (see **Figure 3**), but it is now widely used to delineate pathology outside of the brain, exploiting differences in blood vessel density and vascular permeability. Diagnosis may be based on the standard enhanced images, but often contrast is improved by subtracting post-contrast from pre-contrast images, or by performing fat-suppressed imaging.

More complex approaches exploit the dynamic behaviour of contrast agents to obtain physiological information, discussed further below. In some tissues, magnetization transfer techniques are employed to further improve contrast. While many agents are in development, the other major class of agent in clinical practice is positive (T_1) liver agents such as gadoterate meglumine (Gd-DOTA) (taken up in tumour) and Mn-pyridoxal-5'-phosphate DPDP (taken up in normal liver cells) and negative (T_2^*) liver agents such as superparamagnetic iron oxide particles (SPIO) which are taken up by the mononuclear phagocytosing system (Kupffer cells), reducing signal from normal liver (**Figure 4**).

Measuring Physiology and Function

The nature of magnetic resonance measurements confers sensitivity to a range of properties of water molecules that can be exploited to measure functional aspects of tissues and fluids. Probably the most widely used feature is the sensitivity of MR measurements to motion. When imaging static tissues, motion of fluids or of other tissues presents as a problem to be minimized so as to reduce artefacts. The most common effect is misregistered signals at the same frequency (same position in the read-out direction) but displaced in the phase-encoding direction. This effect can be reduced by the strategies discussed above or by the use of gradient motion rephasing

Figure 3 Transaxial images through the brain of a patient with a glioma. (a) T_1 -weighted spin-echo sequence showing a large tumour in the deep cerebral white matter. (b) The same slice following injection with 0.1 mmol kg^{-1} of gadolinium contrast agent. In the latter slice, the sequence also had gradient moment rephasing to reduce artefacts from flowing blood, causing a slight change in white/grey matter contrast.

Figure 4 Transaxial images through the liver of a patient with hepatic metastases from colon cancer. (a) Breath-hold FLASH T_1 image ($TR = 80$ ms, $TE = 4.1$ ms, $\alpha = 80^\circ$) showing limited lesion contrast. (b) Proton density-weighted FLASH image ($TR = 127$ ms, $TE = 10$ ms, $\alpha = 40^\circ$) showing darkening of the liver from application of $15 \mu\text{mol kg}^{-1}$ of superparamagnetic iron oxide contrast agent, increasing the conspicuousness of the lesion.

sequences, where the phase gain resulting from movement in the gradient is cancelled by reversed-polarity gradients. Subtraction of pairs of images with and without these additional gradient-lobes results in images of the moving material. The flow of fluids can be measured by bolus-tracking techniques, where a slice is saturated and inflow is observed, or where a distant slice is tagged (by inversion, for example) and the appearance of the tagged blood in the slice of interest is observed. Alternative approaches make use of the phase gain occurring in moving fluids, allowing the speed and direction of flow to be calculated from phase maps (Figure 5). Specific sequences can directly measure flow profiles in any arbitrary direction. These techniques are used to make direct measurements of flow velocity, cardiac valve performance, vessel patency and the effects of obstruction, but can also be used to produce flow images.

Based on these flow-sensitive techniques, a major area of MRI development and application has been MR angiography. A range of time-of-flight and phase-contrast

Figure 5 Flow-sensitive images of blood flow. (a) An oblique coronal phase-contrast image through the ascending and descending aorta, where white shows flow out of the heart and up the ascending aorta, dark shows flow downwards, through the descending aorta. (b) A 3D FLASH image using navigator echo techniques to remove motion effects, showing the right coronary artery just above the aortic arch (the thin white vessel seen against a dark background, centre left of image). Both images were acquired with ECG triggering.

techniques are used to produce 3D data sets, or direct projection views, of vascular structure. 3D data sets are usually processed to produce a set of maximum intensity projections (MIPs), at different orientations, which can then be presented as a cine-loop display, giving apparent 3D visualization of vascular structures. The sensitivity of the measurement techniques has been improved with travelling saturation sequences and by the use of contrast agents and bolus-tracking approaches (Figure 6). A major advantage of MR angiography (MRA) is that registered high-resolution soft-tissue images can be obtained at the same time, aiding resolution of diagnostic problems. Initially the major area of interest was in carotid artery stenosis and in vascular abnormalities in the brain. Advances in technique now allow major vessels to be evaluated throughout the body, including the lung and peripheral vascular disease (Figure 7). It is now possible to use such approaches to replace expensive diagnostic angiography in application including screening for brain aneurysms and selection of donors for renal transplant.

While MRI is sensitive to bulk flow in vessels, it is also possible to assess the slower nutritive blood supply or perfusion of tissues, together with vascular permeability,

Figure 6 A maximum intensity projection of a set of MR time-of-flight angiography images, showing aneurysms on the circle of Willis (bright areas left and right of brain centreline).

and to measure the diffusion of water molecules within tissues. Diffusion is usually measured by determining the loss of signal resulting from the additional dephasing of magnetization experienced by spins moving in a magnetic field gradient. Initially this was achieved by strong pairs of gradients on either side of the 180° pulse in a spin-echo sequence, resulting in moving spins receiving a net dephasing, whereas the phase change cancelled for static spins. The loss in signal is proportional to the diffusion coefficient, but is also affected by the dimensions of the structures in which the spin can move in the time available, leading to the term apparent (or restricted) diffusion coefficient (ADC). Early measurements with this approach showed that by sensitizing the gradients in different directions, it was possible to demonstrate the orientation of white-matter tracts in the brain. Molecules travelling along the tracts could travel a considerable distance, leading to a large loss of signal, whereas those travelling across the tracts could not move far, resulting in little loss of signal. This provided a powerful tool for analysing brain structure *in vivo*, and for better understanding of anatomical distortion due to disease. In early machines, the techniques were very susceptible to eddy currents induced in the magnet by the large gradient pulses, and by small bulk movements in tissues and fluids, which could give rise to much greater signal changes than the diffusion itself. These

Figure 7 A maximum intensity projection of a set of MR contrast-enhanced angiography images obtained from a 3D FISP sequence, following administration of a gadolinium contrast agent. The image shows the renal arteries and descending aorta (bright centre right with downward-angled renal arteries) and more faintly the upward-angled renal veins and kidneys, draining into the inferior venacava (centre left). The right kidney (to the left of the image) is reduced in size owing to involvement of a renal carcinoma (dark outline visible). At the top of the image the pulmonary veins can be seen clearly.

problems have been largely overcome by real-time imaging sequences and improved hardware. Diffusion measurements now commonly apply a set of six differently gradient-sensitized sequences to evaluate both the magnitude and spatial distribution of restricted diffusion, providing a diffusion tensor measurement. The method is now of considerable importance in the diagnosis of stroke and other ischaemic disease, where increased diffusion is an early and sensitive indicator of insult, providing the possibility of early and effective intervention before cell function is irreversibly lost.

Perfusion has also been measured using variants of the tagging or outflow techniques described above, where signal or apparent relaxation time changes occur as a result of the inflow or outflow of labelled spins. Contrast-enhanced studies provide a tracer, allowing the inflow or washout of the tracer, as seen on T_1 weighted images, to be used to derive perfusion. This approach is complicated for those positive contrast agents currently licensed for clinical use (gadolinium-labelled chelates) as they equilibrate rapidly with the extracellular space and also relax water molecules that distribute between the

extracellular space, intracellular space and vascular space. Future generations of blood pool agents will be more effective in measuring perfusion as their distribution will be limited to the vascular space. An alternative, and more effective, approach is to make use of the local change in magnetic susceptibility that occurs as a bolus of high-concentration contrast agent passes through the vascular bed. Prior to the contrast agent equilibrating between the intra- and extravascular space, there is a large susceptibility gradient around each capillary, which will result in signal loss due to dephasing on gradient-echo sequences. Using T_2^* -weighted fast-imaging sequences, this transient phenomenon can be detected. It is proportional to the blood volume in the image, and the timing is related to blood flow (**Figure 8**).

By using T_1 -weighted images with positive extracellular contrast agents, combined with modelling techniques, it is also possible to calculate the volume of the extravascular extracellular space, and to calculate the permeability–surface area product governing the rate of transfer of the contrast agent out of the vascular system. This measure is of particular interest, as developing tumour vasculature is characteristically leaky. Development of this new vasculature by tumour-initiated growth factors is believed to be a necessary condition for tumour growth above the limit at which nutritional requirements can be supplied by simple diffusion, and is a target for new generations of anti-angiogenic therapies. Permeability and vascular volume can be calculated on a pixel-by-pixel base as colour-mapped functional images and superimposed on anatomical images. Such measurements require quantitative imaging sequences. Much useful information can be obtained by characterizing the behaviour of contrast uptake and washout, and studies have shown that this can be of value in identifying and characterizing tumours, and in monitoring response.

MRI also provides a number of approaches by which tissue motion can be measured. In principle, phase maps or tagging can be employed, although, owing to slice thicknesses larger than or comparable to the motion, this is rarely done. A more widely used approach in cardiac wall motion studies is the application of a one- or two-dimensional criss-cross pattern of parallel signal-suppressed lines on the object. After a defined period, short compared with T_1 relaxation, an image is read out and the movement of tissue relative to the original grid can be deduced. Appropriate software can provide for sophisticated wall motion studies (**Figure 9**). Associated with techniques for monitoring ventricular function based on flow, tissue perfusion studies and assessment of cardiac artery patency (see **Figure 5**), these provide a powerful range of techniques for cardiology.

A more recent area of development has been the generation and application of hyperpolarized gases. Both ^3He and ^{129}Xe can be prepared at high nuclear

polarizations (10–50%) compared with ^1H (0.0006% at 1.5 T). This provides a very high signal, and initial measurements have shown the potential to image the lung air-spaces. This complements advances in fast very short echo-time sequences that have allowed the lung parenchyma to be imaged, as well as MRA approaches imaging the lung vasculature. Most measurements have been made with ^3He , which has low solubility in tissues. ^{129}Xe is of particular interest in measuring perfusion and other properties of tissue spaces, where it demonstrates a large tissue composition-dependent chemical shift. The potential for intravenous delivery using perfluorocarbon blood-substitutes and other suitable media has been evaluated. Studies using hyperpolarized gases require new imaging approaches, as the polarization is exhausted by sampling and signal can only be restored by delivery of fresh hyperpolarized gas.

Functional MRI (fMRI)

A major new area of functional MRI has been the discovery that brain activity associated with specific functional tasks causes a change in MR signal observable on T_2^* -weighted imaging sequences. This is believed to result from brain activation causing increased local blood flow, which then provides an increased oxygen supply exceeding the increased demand. The blood thus contains proportionately less paramagnetic deoxyhaemoglobin, reducing the susceptibility between blood and surrounding tissues and thus reducing the susceptibility-induced signal loss. This approach provides higher-resolution images than the positron emission tomography techniques used previously and allows functional activation measurements to be related to high-resolution images of local anatomy. Typically imaging is conducted with and without a stimulus, with subtraction or comparison of the two image sets to provide a difference image demonstrating the region of activation (**Figure 10**). Single-shot techniques are now being developed. The approach is being employed for basic neurological and psychiatric research, as well as in conditions affected by brain function. Signal-to-noise improves with field strength, and a number of centres are exploring the application of higher-field machines to improve the quality of these measurements. As with many of the more advanced techniques, motion and registration between measurements present problems, and sophisticated motion correction, image registration and mapping techniques are being developed.

There are several main areas where fMRI shows promise. The first application is in fMRI-guided neurosurgery such as to maximize the safety of tumour resections, tissue ablation or stimulation, and to identify specific loci for surgical resection in epilepsy. The second

group of applications comprises the use of fMRI for improved understanding of disease, such as imaging migraine aura progression, defining phenotypes of behavioural disorders, identifying disease mechanisms and allowing novel *in vivo* markers of functional polymorphisms. fMRI also has potential in clinical management such as evaluating disease risks, in Alzheimer's disease for instance, in providing markers of diseases such as schizophrenia where there is a distinct lack, and in predicting and assessing response and relapse after treatment. Finally, fMRI might have uses as part of drug discovery and development processes. This might involve selection of suitably responding patients for clinical trials, providing information on pharmacokinetics and pharmacodynamics and even investigation of placebo effects.

MR spectroscopy (MRS) provides a complementary means of studying tissue function and metabolism. In the past, spectroscopic examinations have often been distinct from imaging studies, but the increase in imaging speed, increased automation and more robust instrumentation have allowed spectroscopy to be integrated with imaging examinations. This trend will continue, allowing specific metabolic pathways, tissue metabolism via ^1H or ^{31}P spectroscopy, and drug distribution studies to be integrated with measurements of perfusion, diffusion or activation.

Interventional Techniques

The development of methods of guiding interventions or operations is a growing area of MRI. Following identification of suspicious lesions by MRI, it is often necessary to sample tissue to allow cytology or histopathology. Where MRI has provided better imaging, it is desirable to perform sampling using MRI, and eventually this might occur at the diagnostic visit. The design of most

Figure 10 A set of processed image planes through the head of a volunteer showing (black) areas of significant neural activation following exposure to a pure audio tone. Activation data were obtained at The Royal Marsden Hospital by Mr D. Collins using a real-time echo planar imaging (EPI) sequence, and processed at the Institute of Psychiatry by Dr J. Suckling.

clinical MR systems using a cylindrical superconducting magnet design has limited access to the patient or biopsy site, presenting difficulties in performing biopsy or fine-needle aspirates in the magnet. A number of approaches have now been developed. MR-compatible biopsy tables designed for particular organs, often using specialist coils, are available for use with conventional systems. The breast is one such region, where MRI is demonstrating high sensitivity for the detection of breast cancer. Magnets have also been designed to provide open access, so that they can be used in the operating theatre or for more conventional image-guided sampling. These systems employ either C-configuration magnets at about 0.2 T or a dual-doughnut superconducting design at 0.5 T, allowing access between the two superconducting rings. A particular objective of this latter design has been to enable interactive image guidance during neurosurgery. These approaches are requiring the development of a wide range of MR-compatible accessories, together with rapid imaging techniques and display technology.

Minimally invasive therapeutic approaches are also being piloted with MRI guidance and monitoring. These methods include high-intensity focused ultrasound, laser, electric current, RF hyperthermia and cryoablation. Areas of interest include breast, prostate and liver cancer. In principle, MR provides a valuable means of directly measuring temperature distributions in monitoring these treatments, although current techniques require a field strength of 1.5 T to provide adequate signal-to-noise ratio. An extension of these approaches is monitoring of intravascular or intra-gastrointestinal tract using small surface coils providing high-resolution images local to the intervention.

T_2	spin–spin relaxation time

Magnetic resonance imaging (MRI) is a useful, versatile diagnostic tool that can achieve contrast among different tissues by taking advantage of differences in T_1 relaxation times, T_2 relaxation times and proton densities. There has also been considerable interest in the development of MRI techniques as a noninvasive method of measuring blood flow and tissue perfusion in certain clinical conditions. MRI flow measurements have been applied particularly to the vascular system and compared with other techniques, such as ultrasound. MRI provides a noninvasive method for quickly measuring velocity and volume flow rates *in vivo* using readily available methods and equipment. Flow quantification by means of MRI does not require the use of ionizing radiation and/or contrast agents, as X-ray techniques do. Unlike ultrasound, MRI measurements are not hindered by the presence of overlying bone and air.

The two principal methods of velocity measurement use either ‘time of flight’ or ‘phase contrast’ techniques. Time-of-flight methods are well suited for determining the presence and direction of flow, and phase-based methods are well suited for quantifying blood velocity and volume flow rate.

Furthermore, MRI offers the opportunity to quantitatively assess properties of tissue, such as perfusion and blood volume. Use of such quantification potentially allows tissue to be characterized in terms of pathophysiology and to be monitored over time, during the course of therapeutic interventions.

Magnetic Resonance Flow Measurements and MR Angiography

Time of Flight

On cine gradient-echo images, blood flow is bright. The high signal intensity (bright signal) of vessels on cine gradient-echo images is achieved by the entry of unsaturated protons into the image, a phenomenon called time-of-flight or flow-related enhancement. By

displaying flowing blood as high signal intensity, cine gradient-echo images generally provide a better signal-to-noise ratio within the blood pool than spin-echo images, which demonstrate the arterial lumen as a dark region of signal void. Because the signal in cine gradient-echo imaging is based on through-plane movement of protons, this technique is occasionally less sensitive to slow flow or flow within the imaging plane (in-plane flow). In cases where blood flow is slow, the vessel is tortuous or flow is primarily in-plane, there may be diminished signal or even complete signal saturation on cine gradient-echo images.

However, signal loss on cine gradient-echo images can be used as a diagnostic aid in special circumstances. In cases of haemodynamically significant stenosis (as in aortic coarctation or aortic stenosis), a dark, fan-shaped flow jet can be seen on cine gradient echo images. This area of intravoxel dephasing results from the turbulent flow typically seen distal to a significant vascular narrowing. Aortic insufficiency may also manifest as a flow jet on cine gradient-echo images. Although the relative size of the jet has been shown to correlate with the clinical severity of the stenosis, the appearance of the jet is highly variable and can be greatly affected by a variety of factors (e.g. imaging plane, pulse sequence, echo time). The jet may be small or even absent despite the presence of a high-grade (haemodynamically significant) vascular narrowing.

Phase Contrast (PC)

One good method for quantitatively measuring blood flow assesses the change in phase of the blood signal as the blood flows through a slice oriented perpendicular to the direction of flow. This method derives velocity from the phase of the MR signal, and calculates volume flow rate by multiplying the average velocity by the vessel’s area. To determine flow velocity, cine PC imaging takes advantage of the phase shifts experienced by moving protons (within blood) as they move along a magnetic field gradient. Bipolar flow-encoded gradients are applied to measure these phase shifts. This technique requires the operator to prescribe a velocity encoding that determines the flow-encoding gradient strength and sensitivity to flow direction(s) (anterior-to-posterior, anterior-to-posterior and left-to-right), which dictate the plane(s) of the gradient application.

The vascular information from cine PC acquisitions may be displayed as simple angiographic images (similar to cine gradient-echo images) in which all flow is bright or as phase map images in which the flow directional information is coded as bright or dark and the flow velocity data are reflected in the signal intensity (relative brightness or darkness). With phase map cine PC imaging, blood flow can be quantified (millilitres per minute).

Ideally, if flow measurement is desired, one should choose an imaging plane perpendicular to the direction of the flow, select a velocity encoding at least as high as the fastest expected flow velocity, and prescribe the flow sensitivity to be in accordance with the direction of desired flow measurement. For measurement of normal flow within the ascending or descending aorta, for example, an axial cine PC prescription with a velocity encoding of 150 cm s^{-1} and superior-to-inferior flow direction is appropriate. If slow flow is expected or the goal is to visualize flow in a false lumen, a lower velocity encoding such as 50 cm s^{-1} may be more appropriate.

MR Angiography (MRA)

Angiography is the imaging of flowing blood in the arteries and veins of the body. In the past, angiography was only performed by introducing an X-ray opaque dye into the human body and making an X-ray image of the dye.

Many techniques have been developed for MRA of the great vessels, including gradient echo time-of-flight and phase-contrast techniques. Both time-of-flight and phase-contrast MRA methods can be implemented as either a sequential 2D or a true 3D acquisition. The encompassed MRA volume is analysed by postprocessing with a maximum intensity projection (MIP) technique or with multiplanar reformatting (MPR). The MIP technique allows a rotational '3D' display of the vessel, viewed from different angles. MPR allows reconstruction of parallel thin slices in any orientation.

Three-dimensional gadolinium-enhanced MR angiography can substantially improve the resolution, signal-to-noise ratio, speed and overall quality of vascular MRI. 3D gadolinium-enhanced MRA achieves its image contrast and hence its angiographic information from the T_1 -shortening effect of gadolinium on blood water protons. Because it is less dependent on inherent blood flow characteristics for the generation of vascular signal, 3D gadolinium-enhanced MRA is minimally degraded by flow-related artifacts. Three-dimensional gadolinium-enhanced MRA can be performed quickly (within a 20–40-s breath hold) on high-performance MR imagers. With a computer workstation, data from 3D gadolinium-enhanced MRA can be postprocessed to generate projection aortograms in any obliquity, which are similar to conventional angiograms (Figure 1).

MRA is used routinely in many centres for evaluation of the carotid arteries and intracerebral vasculature, aortography and assessment of the iliofemoral system. MRA of the coronary arteries is technically more difficult due to their relatively small size, their complex 3D anatomy and their constantly changing position within the thoracic cavity due to cardiac motion and respiration.

Tissue Perfusion

In the broadest sense, perfusion refers to one or more of various aspects of tissue blood flow. Parenchymal blood flow is the ratio of blood volume to the transit time of blood through the tissue. The different techniques of MR perfusion typically deal with blood volume, transit times and blood flow as relative measures, although absolute quantification may also be possible. The two perfusion

Figure 1 3D gadolinium-enhanced MR angiography of the abdominal aorta (a) and pulmonary vessels (b).

strategies are based either on induced changes in intravascular magnetic susceptibility (T_2^* effect) or on relaxivity (T_1 effect) and on tagging inflowing arterial spins.

Dynamic Contrast-Enhanced MR Imaging

Dynamic contrast-enhanced MRI is a method of physiologic imaging, based on fast or ultrafast imaging, with the possibility of following the early enhancement kinetics of a water-soluble contrast agent after intravenous bolus injection.

Bolus tracking techniques have been used to measure tissue perfusion, notably in the kidney, heart and brain. These methods are based on fundamental MR contrast mechanisms that promote either T_1 or T_2/T_2^* enhancement. Gadolinium chelates administered in low doses lead to predominantly T_1 -weighted signal increases, mediated by water proton–contrast agent dipolar relaxivity interactions. Alternatively, the T_2/T_2^* dephasing of spins, due to a locally heterogeneous high magnetic susceptibility environment, has been exploited by using higher doses of gadolinium. If the curve of concentration versus time can be plotted as a known quantity of a tracer passes through an organ, organ perfusion can be calculated from the area under the curve. Alternatively, if the tracer is wholly extracted by the organ, the principles described by Sapirstein enable perfusion to be measured from the amount of tracer trapped by the organ.

In the normal brain, tight junctions of nonfenestrated capillaries effectively prevent Gd chelates from leaking into the interstitial space. Thus during bolus-tracking experiments, Gd-DTPA behaves like a true intravascular contrast agent as long as there is no brain abnormality that causes blood–brain barrier disruption, and regional cerebral blood volume may be determined by integrating the time-versus-concentration curve. As opposed to perfusion imaging of the brain, in other tissues such as the breast the technique is hampered by the fact there is nothing like a blood–brain barrier. Accordingly, Gd-DTPA will not be a true intravascular contrast agent. Nevertheless, by treating it mainly as an extracted tracer, it is possible to measure perfusion from the peak tissue enhancement. The model assumes a linear relation between tracer concentration and signal enhancement. Now that echo planar and ultrafast gradient-echo imaging can provide at least one image for each cardiac cycle during the passage of the tracer, measurement of myocardial perfusion with high resolution is possible.

Arterial Spin Labelling

Blood flow imaging with MR by spin labelling, or spin tagging, of the water protons in the arterial source to a slice has the advantage that it is completely noninvasive,

is a more direct assessment of blood flow, and may generate absolute blood flow quantification. Cerebral blood flow quantification has been accomplished by continuous adiabatic inversion of arterial spins and use of tracer kinetic models of cerebral blood flow determination. Qualitative cerebral blood flow mapping has also been described using echo planar sequences, a single inversion pulse to inflowing arterial spins, and subtraction of tagged and untagged echo planar images. In principle it is also quantifiable, to give absolute flow quantification.

Clinical Applications

Brain

Hyperacute stroke

Whereas conventional computed tomography and MRI are excellent modalities with which to detect and characterize central nervous system disease, they fail to depict acute ischaemia and infarction reliably at its earliest stages. Detection of cerebral infarction by dynamic MR contrast imaging is possible. Some of the most promising work has been done with perfusion and diffusion imaging. Perfusion MRI characterizes how much brain tissue an occlusive blood clot has placed at risk (see **Figures 2** and **3**), whilst diffusion measurement shows how much tissue is already damaged or is possibly even dead.

Flow-restrictive lesions

MR volume flow rate measurements have been used to evaluate the severity and haemodynamic significance of flow-restrictive lesions in the carotid, vertebral and intracranial vessels. A severe stenosis can result in a significant decrease in volume flow rate distal to the stenosis. Because brain perfusion relates directly to the volume of blood delivered, identifying an area of decreased volume flow rate distal to a stenosis may be of clinical importance.

Intracranial volume flow rate measurements are technically difficult using methods other than MRI, and for this reason the normal volume flow rates for intracranial vessels are not well established.

Vascular flow reserve

Another evaluation process measures the change in volume flow rate in a given vessel before and after vascular challenge. In normal situations, inhalation of CO_2 or intravenous injection of a vasodilator (acetazolamide), causes intracranial arteries to dilate, leading to an increase in flow velocity and volume flow rates in these vessels. The difference between the flow rate under routine conditions and maximal flow rate after chemically induced vasodilatation is designated as the flow reserve. In human subjects and specifically in patients with cerebrovascular disease the acetazolamide test is

Figure 2 Brain axial spin-echo T_2 -weighted image (a) and sequential dynamic susceptibility-contrast in a patient with a right infarct (b).

performed to evaluate the decrease in cerebral perfusion pressure through the investigation of the vasomotor reactivity (VMR), which is thought to reflect compensatory vasodilatation. In patients with occlusion or stenosis of more than 90% of the internal carotid artery, diminished VMR was reported to be significantly associated with low flow infarctions and higher rate of future ipsilateral stroke compared with patients with a normal or only slightly disturbed VMR. The quantification of the

response of the blood vessels to the stimulus can be obtained by measuring cerebral blood flow, cerebral blood volume or blood flow velocity.

Subclavian steal

In this syndrome due to occlusion of the subclavian artery proximal to the origin of the vertebral artery, the blood flow is reversed in the vertebral artery and re-directed from the basilar artery into the arm. Phase

Figure 3 Change in signal intensity during a rapid bolus contrast injection (T_2^* effect) comparing normal brain and ischaemic regions. The lesion shows a less dynamic decrease in signal intensity than the contralateral normal region.

contrast MRI can be used to determine the direction of vertebral artery flow. This information is valuable for monitoring the progression of disease, for assessing the magnitude of the steal, and in the postoperative setting, for determining the efficacy of vascular reconstructive surgery.

Cerebrospinal fluid flow

Phase contrast methods have been used to measure velocity and volume flow rates of cerebrospinal fluid in healthy volunteers and in patients with various diseases. This method can be used to measure the flow rate of cerebrospinal fluid through ventriculo-peritoneal shunts in patients with hydrocephalus (Figure 4).

Thorax

Valvular heart disease

The signal intensity of flowing blood during cine gradient-echo imaging depends upon the nature of the flow. In general, flowing blood generates uniform high signal because of continuous replacement of magnetically saturated blood by fresh blood. Turbulence leads to loss of signal and so the turbulent jet of mitral regurgitation can be seen in the left atrium. The size of the signal void can be used as a semiquantitative measure of regurgitation but the signal void will vary with imaging parameters such as echo time. This is similar to colour flow Doppler where technical factors such as gain adjustment and filter setting are important. A more fundamental problem common to both is that the size of the regurgitant jet is influenced by many factors in addition to the severity of regurgitation, such as the shape and size of the regurgitant orifice and the size of the receiving chamber.

Figure 4 Phase contrast image in a patient with a brain tumour before (a) and after (b) surgery. Before surgery no flow is seen in the third ventricle because of tumour compression. After surgery flow can be seen in the floor of the third ventricle (arrow).

Myocardial perfusion

MRI can be employed to evaluate myocardial perfusion at rest and during pharmacological testing. Ultrafast MRI sequences with image acquisition at every heart beat provide the opportunity to acquire dynamic information related to the passage of a paramagnetic contrast agent through the myocardial microcirculation and thus provides an indirect measure of myocardial perfusion (Figure 5). A myocardial region supplied by a severely stenosed coronary artery can be detected by a delayed increase in signal intensity and a decreased peak signal intensity. Several tomographic images can be acquired

Figure 5 Selected T_1 -weighted images, of a single short-axis section, illustrating myocardial transit of the contrast agent in the left ventricle (top images). Myocardial perfusion is difficult to assess visually. However, postprocessing the image (factor analysis) demonstrates myocardial enhancement (bottom image).

during a unique bolus of a small amount of paramagnetic chelate allowing the study of almost the entire myocardial volume compared to the previous situation where only one slice was available.

Great Arteries

Aorta

Next to congenital heart disease, the clinical utility of flow MRI has been most convincingly documented in patients with large vessel disease, and more specifically with acquired aortic disease. The wide field of view and the ability to freely adjust the orientation of imaging planes to the vessel direction do not only favour a clear depiction of the anatomy of the vessel lumen and vessel wall, but also facilitate the understanding of the relation to other anatomic structures within the chest and ensure highly accurate dimensional measurements.

Furthermore, it is relatively easy to combine the morphological information with functional aspects on blood flow, which can be assessed both qualitatively and quantitatively. The increased flow rate in arteries during systole, and in veins during both systole and diastole, enhances the contrast between intraluminal blood flow and vessel wall. Thus, a good image quality is usually obtained even without administration of intravenous MR contrast material.

Gradient echo techniques and phase velocity mapping are useful for demonstration and characterization of mural thrombus and for qualitative and quantitative assessment of aortic regurgitation associated with aneurysm of the ascending aorta.

There is substantial evidence demonstrating that from all the available modalities MRI has the highest sensitivity and specificity for detection of aortic dissection.

MRI is not only well suited to identify an intimal flap, but can also detect aortic regurgitation and pericardial effusion with high accuracy.

The extent of aortic dissection is readily detected by NMR imaging and is displayed including involvement of other vessels. The entry and exit points are more difficult to localize, but there is no doubt that invasive investigation can be avoided with a combination of echocardiography and NMR imaging.

Pulmonary arteries

The retrosternal position of central pulmonary arteries makes it difficult to assess pulmonary blood flow by Doppler echocardiography, especially in the presence of skeletal or lung abnormalities. NMR velocity imaging is not technically constrained and is capable of accurate blood flow measurement in any plane. Flow can be accurately quantified in the left and right main pulmonary artery with use of phase velocity mapping.

MR velocity mapping is an accurate technique to measure volumetric pulmonary flow after repair of congenital heart disease. The consequences of pulmonary regurgitation on right and left ventricular function can be comprehensively evaluated by the combined use of MR velocity mapping and gradient-echo MRI of both ventricles. This unique information may have prognostic and therapeutic implications for the management of patients with (repaired) congenital heart disease.

The flow pattern in the main pulmonary artery differs between normals and patients with pulmonary hypertension. The latter have lower peak systolic velocity and greater retrograde flow during end systole.

Studies have indicated the possible role of MRI in detecting central pulmonary emboli with the use of conventional MRI techniques. MRA using fast

2D time-of-flight gradient-echo techniques combined with maximum intensity projections showed good sensitivity but only moderate specificity. Better results may be obtained with the use of phased-array coils or 3D MRA. Gadolinium-enhanced MRA of the pulmonary arteries, as compared with conventional pulmonary angiography, had high sensitivity and specificity for the diagnosis of pulmonary embolism. This technique shows promise as a noninvasive method of diagnosing pulmonary embolism without the need for ionizing radiation or iodinated contrast material.

Tumours

Dynamic contrast-enhanced MRI has been used as an additional imaging technique in various clinical applications, such as differentiation of benign from malignant lesions, tissue characterization by narrowing down the differential diagnosis, identification of areas of viable tumour before biopsy and detection of recurrent tumour tissue after therapy. This technique provides information on tissue vascularization, perfusion, capillary permeability and composition of the interstitial space.

Diagnosis in dynamic contrast-agent-enhanced breast MRI is primarily based on lesion contrast-agent-enhancement velocity, with breast cancers showing a faster and stronger signal intensity increase after contrast injection than benign lesions. The rapid enhancement seen in carcinomas is thought to be due to the angiogenic potential of malignant lesions.

While the dynamic technique proves very sensitive, specificity remains a problem. Initial experiences with dynamic contrast-enhanced breast MRI suggested a clear-cut separation of benign and malignant lesions on the basis of their enhancement velocities and the approach will have to be reviewed if benign lesions have enhancement velocities comparable to or even higher than those of malignant tumours.

Kidneys

MRI has advantages over both computed tomography and nuclear scintigraphy for assessing renal function, because it combines high spatial resolution with information on perfusion and function. Quantification of flow rate by phase contrast in the renal arteries and veins has the potential to provide estimation of renal blood flow, which could prove useful in a number of clinical situations, especially for studying renal vascular disorders

and the effects of treatment, and for assessing renal transplants. Evaluation of renal perfusion with MRI has become feasible with the development of rapid data acquisition techniques, which provide adequate temporal resolution to monitor the rapid signal changes during the first passage of the contrast agents in the kidneys. Magnetically labelled water protons in blood flowing into kidneys has been used to noninvasively quantify regional measurement of cortical and medullary perfusion. Dynamic MRI demonstrates renal morphology and reflects the functional status of renal vasculature. The measurement of renal perfusion by MRI could provide a non-invasive diagnostic method for monitoring the status of renal transplants and renal ischaemic lesions.

Conclusion

With the above developments, the outlook for magnetic resonance flow measurements and contrast-enhanced MRI is bright. The opportunity to extract quantitative regional physiologic information in addition to anatomic information will definitely elevate MRI from 'anatomic imaging with soft tissue contrast' to 'a noninvasive technique for assessment of physiologic processes and tissue integrity with high spatial resolution', offering new power for diagnosis and treatment monitoring, and insights into the very mechanisms of disease pathophysiology.

Synopsis

Since 1973 when Paul Lauterbur published the first practical magnetic resonance imaging (MRI) method in *Nature* the one constant in this exciting area of science has been the rapid pace of change. Novel MRI methods forced the development of new technologies such as pulsed field gradients which have, again, opened the field to even more exciting pulse sequence developments. There has been a vast improvement in image quality since the early days of the subject. Obviously many factors have contributed to this improvement and these will be discussed individually below. However, one factor stands pre-eminent and that is the improvement in pulsed magnetic field gradient technology. Improvements in gradient coil design have meant that gradients have become more linear and more sensitive, and the introduction of gradient shielding technology has reduced the problems of pre-emphasis and B_0 correction to a thing of the past except for the most demanding methodologies. And, of course, there have been major innovations in gradient amplifier technology shortening rise times, increasing gradient strength and reducing gradient noise. Other major innovations that have significantly improved image quality have been the introduction of birdcage resonators and phased array coils. Oversampling of the receiver signal by the analogue-to-digital converter (ADC) has allowed the introduction of digital filtering techniques that prevent the folding of noise from outside the spectral width of interest back into the image. And, of course, there have been some technology improvements that have not contributed directly to improvements in image quality but have made the MRI technique easier to implement such as the introduction of self-shielded magnets and the enormous increase in computer power that has made 3D MRI techniques practical in terms of 3D Fourier transforms and image processing and display.

Introduction

NMR spectrometers can be converted into MR scanners by the addition of gradient handling capacity and gradient amplifiers. In the crudest configuration the output of the gradient amplifiers can be fed into the room temperature shim set to create the linear magnetic field

gradients necessary for imaging. Thus, modern NMR spectrometers with triple axis gradient sets can be used for micro imaging.

However, for biological and clinical MRI applications there are a number of additional hardware items that need to be considered. The basic components of the typical clinical superconducting MR scanner can be seen in **Figures 1** and **2**. The individual components are described in more detail in the text, but briefly, the magnet cryostat is kept at liquid helium temperature and houses the windings of the primary magnet and, if active shielding is used, a second set of superconducting coils outside the primary coils to reduce the fringe field effect. Inside the magnet bore, clinical scanners will usually have a passive shim assembly, active shim coils, gradient set, RF whole body coil and patient bed. Typically, the RF coils will be tuned to the proton frequency; however, the addition of RF coils tuned to other nuclei and the appropriate RF amplifiers will allow such nuclei to be imaged if the signal-to-noise ratio is sufficient.

Magnet

Bore

First, one needs to decide the largest patient size that needs to be scanned, as this will govern the magnet bore size. There is a roughly two to one relationship between bore size and tractable patient diameter. Most clinical whole body scanners have a 1 m bore, but specialist magnets exist for imaging larger patients. Head only scanners will typically have a diameter of 60 cm. For smaller animals such as rats and rabbits a range of smaller bore magnets exists.

Field

As with conventional high-resolution NMR, higher field strength produces more signal. However, for imaging applications this must be tempered by the consideration that differences in T_1 are generally greater at low field strengths and therefore images from lower field magnets intrinsically have more contrast. For micro-imaging applications where pixel size is approaching the distance water can diffuse during the application of the pulse sequence; practical experiments generally require field

Figure 1 Schematic cross-section through a typical superconducting clinical MR scanner. Within the cryostat (light blue) are the superconducting coils of the primary magnet (red) and active shield (green). In the bore of the magnet there are passive shim rods (grey), active shim coils (orange), gradient set (blue), whole body RF coil (black) and patient bed. The tractable diameter is generally half the magnet bore diameter.

Figure 2 The essential components of a typical clinical MRI system.

strengths in excess of 7 T. However, in the clinical realm superb images may be produced on systems with 0.5 T fields.

Type

There are three types of magnets used for MRI.

Superconducting

Higher field magnets are superconducting (**Figure 3**). The magnet coil sits in a pool of liquid helium at 4.2 K. In most animal imaging systems this is surrounded by a secondary liquid nitrogen temperature dewar (77 K) to reduce heat transfer to the liquid helium dewar (liquid helium is much more expensive than liquid nitrogen). Typically, the liquid helium would need to be topped up at intervals of 3 to 12 months. Liquid nitrogen is usually filled weekly. Modern clinical systems dispense with the secondary cryostat in favour of a helium refrigerator. These systems still need periodic refilling with liquid helium, generally at yearly intervals. The superconducting magnet offers high field strength, stability and homogeneity; however, the initial cost of the magnet can be an order of magnitude more than the electromagnets and permanent magnets and the extensive fringe field can make finding an appropriate installation site difficult.

Electromagnets

Resistive magnets have less extensive fringe fields than superconducting magnets but require up to 60 kW to

Figure 3 Actively shielded 2.0 T whole body superconducting magnet. Reproduced by permission of Oxford Magnet Technology, Oxford, UK.

produce fields of 0.3 T and consume large quantities of cooling water (**Figure 4**). The open access design can be ideal for interventional MRI applications. Their main drawback, aside from the limited field strength available, is field instability due to fluctuations in the power supply and temperature.

Permanent Magnets

Like the electromagnet, the field strength of permanent magnets is restricted to 0.3 T. For many applications this will be sufficient and, given the insignificant fringe

magnetic field and open access design, will prove an ideal solution for some installations, particularly where the power supply and/or supply of cryogenics is unreliable. However, permanent magnets require very careful temperature regulation to prevent drifts in field and they can be extremely heavy.

Shielding

The stray fields emanating from superconducting magnets can pose a hazard to the surrounding environment.

Figure 4 Open access 0.24 T resistive electromagnet without cladding. Reproduced by permission of Oxford Magnet Technology, Oxford, UK.

Unauthorized access within the 0.5 mT (5 gauss) field must be prevented to hinder entry of persons with cardiac pacemakers. In addition, fields as low as 0.1 mT can exert deleterious effects on colour computer monitors and analytical equipment such as scanning electron microscopes and mass spectrometers. When space is limited it may be necessary to shield the magnet to reduce its magnetic footprint. Passive shielding can be achieved by encasing either the magnet or the magnet room in ferromagnetic material. This iron shield can be both heavy and expensive. Alternatively, an active shield can be introduced by placing a second superconducting magnet outside the primary magnet and polarised in the opposite direction. The importance of this innovation to the whole body MRI market has been considerable, allowing magnets to be installed on sites throughout the world previously considered unsuitable or uneconomic

and thereby contributing greatly to the overall market growth.

Shim Set

As in high-resolution NMR spectroscopy, it is not sufficient just to have a magnetic field of a certain value in the centre of the magnet. The field also needs to be homogeneous over the volume being sampled. The requirements for imaging are not nearly as stringent as for high-resolution spectroscopy but as the volumes being sampled are generally much larger the demands on the magnet design are equally exacting. Shimming is the process of optimization of the magnetic field homogeneity and is a two-stage procedure. In the first stage, the homogeneity of the primary magnet field is

optimized in the absence of a sample. Magnets will either have several cryoshim coils with windings of different designs inside the cryostat or a series of iron rods placed around the room temperature bore of the magnet to balance imperfections in the field. Generally, the cryoshim currents or passive iron shims need only be adjusted on installation and can thereafter be left unless the magnetic environment changes through, for example, building work.

However, MRI subjects also introduce their own inhomogeneities into the magnetic field as tissue has a different magnetic susceptibility to that of air. These sample-induced field disturbances can be partially removed by the active shims. Small bore and clinical research instruments will typically include an active shim set with perhaps a dozen shim windings. Adjustment of the current in each coil to optimize the magnetic field homogeneity of the sample may be done by hand or by using a simplex minimization routine. Alternatively, one may first map the field inhomogeneities using an imaging method and then calculate the currents necessary to counteract the inhomogeneity in the sample. Many clinical scanners do not have active shim sets but rely solely on DC currents through the gradient set to shim in the X , Y and Z directions.

Magnetic Field Gradients

Among the most critical components of an imaging system are the pulsed field gradients used to encode the images. Here, the characteristics that contribute to high quality images are the spatial linearity of the induced gradient pulses over the volume of interest and the decay characteristics of the gradient pulse. In the simplest system a linear gradient may be induced in the Z -axis by passing a direct current of opposite polarity through a Maxwell pair of coils wound on cylindrical formers. The greater the current, the larger the linear field gradient imposed on top of the primary magnetic field.

Gradient Set

As described above it is possible to make a Z -axis gradient set by winding a pair of circular coils onto a cylindrical former and passing a DC current through the coils such that the polarity is opposed. X and Y gradients can be formed using saddle coils. Today, most gradient sets are no longer wire coils wound onto formers but are streamline patterns etched into copper sheet or cut into a copper plated cylinder. These have the advantage that the fabrication of complex current paths is easier and, generally, they are more compact. There are a number of conflicting parameters that must be considered when designing gradient coils. The sensitivity of the coil (in $\text{Tm}^{-1}\text{A}^{-1}$), the region of acceptable linearity, the

physical dimensions, the impedance and the shielding characteristics (more on this below) must all be weighed in the light of the proposed application. The coils will usually be embedded in epoxy resin to resist the torque generated when current is passed through the coils in the presence of the primary magnetic field. This torque would distort the shape of the coils and is the source of the drumming sound generated when the gradients are pulsed. Water cooling of the gradient set may be necessary for demanding applications with low field of view, thin slices and high duty cycle.

Amplifiers

The gradient pulse strength will be directly proportional to the current fed through the gradient coils. In modern clinical systems with echo planar imaging (EPI) capability the gradient amplifiers may need to produce 600 A. However, even for small animal systems in which the gradient amplifiers are more typically in the range of 50 A, current fed into the coil will take a finite time to reach the plateau value. That is to say that the gradient pulse will not be an ideal square function but will instead be trapezoidal. The duration of this rise time will depend on the inductance of the coil (hence low inductance coils are favoured for their short rise times) and on the voltage of the gradient amplifiers. Some systems are now provided with a 'booster' to raise the voltage and shorten the rise times. This 'booster' is basically a capacitor bank that discharges during the main amplifier switch on, increasing the voltage to drive the current through the coils. However, for fast imaging experiments such as EPI it is still important to minimize inductance in the design of the gradient coils. The other important criterion in selecting gradient amplifiers is low noise characteristics.

Pre-emphasis and Active Shielding

When the gradients are pulsed, residual fields called eddy currents are induced in the cryostat and other metallic structures. These fields decay with time constants typically in the order of tens of milliseconds, but for eddy currents in the cold cryostat vessel wall they may be hundreds of milliseconds long. Eddy currents can have a devastating effect upon image quality unless countered. Increasing the distance between the gradient coil and the magnet bore can reduce them, but as this will reduce the space available for the MRI subject it is often not an option. Eddy currents can be compensated for by overdriving the gradient waveform with a current that will itself counter the effect of the eddy currents. However, adjustment of this 'pre-emphasis' of the gradient pulse can be a tedious business as there are often eddy currents decaying with several different time constants.

Another approach to preventing eddy currents distorting the images is to shield the primary coil with a

secondary coil placed outside the primary coil and connected to it in series. The secondary coil is designed to null the pulsed gradient field of the primary coil everywhere external to the coils but to have minimum effect in the centre of the coil. This approach has been almost universally adopted.

Radiofrequency

As in high-resolution NMR, the nuclei in the MR imaging experiment, be they the water protons of the typical anatomical imaging experiment or other nuclei such as ^{19}F , ^{31}P or ^{23}Na , must first be excited. The requirements for amplitude and phase control of RF pulses are similar to those in high-resolution NMR spectrometers, though the addition of phase coherent frequency switching can be an advantage for multislice fast spin-echo experiments.

RF Amplifiers

Clinical MR scanners used for fast imaging experiments may have up to 15 kW RF amplifiers. These high powers are necessary to reduce pulse duration in fast spin-echo imaging sequences. However, care must be taken that the amplifiers are linear; otherwise the shaped pulses necessary for slice selection will be distorted and the slice profile degraded. Of course, many manufacturers are aware of this problem and compensate their pulse shapes for the known distortions induced by the RF amplifier so that the final pulse shape delivered to the RF coil is optimal. If slice profiles are inadequate, it is always worth checking for non-linearity in the RF amplifiers.

RF Probes

The alternating current generated by the RF amplifier is fed into a probe to create an alternating magnetic field at the Larmor frequency in the sample. There are a number of basic probe types each with their own advantages and disadvantages.

Surface Coils

The simplest type of RF coil is the surface coil. These usually consist of a single loop of wire and give high signal-to-noise ratio for surface structures due to the close coupling of the nuclei in the region of interest and the surface coil. They are used where high signal-to-noise ratio is of primary importance such as in localized spectroscopy experiments, functional imaging and experiments with nuclei other than the proton. The main disadvantage of the surface coil is the loss of signal intensity with distance from the coil, which results in signal intensity variation across the image and a limited field of view.

Volume Coils

Both the Alderman and Grant probe and the birdcage resonator use distributed capacitance to produce a relatively homogeneous RF field in the centre of the probe and hence uniformity of signal intensity across the image (Figure 5). Also, these coils lend themselves to operation in quadrature mode which brings a $\sqrt{2}$ increase in transmission efficiency and a corresponding $\sqrt{2}$ improvement in the signal-to-noise ratio upon reception. Volume and surface coil use can be combined so that the volume coil is used for transmission to produce uniform excitation across the MRI subject and the surface coil is used for reception to increase the signal-to-noise ratio. However, care must be taken that the two coils do not couple to each other, either by ensuring that their fields are orthogonal (geometric decoupling) or by employing active decoupling using additional electronic circuits.

Phased Array Coils

In order to combine the signal-to-noise advantage of surface coils with the larger usable region obtained with volume coils, phased array coils can be used. These consist of an array of coils, each similar to a conventional surface coil, distributed over a surface. Each coil acts independently so that the required output signal can be obtained by combining the outputs from all or some of the elements. In order to reduce interaction between the adjacent coils, each one overlaps its immediate neighbours to minimize mutual inductance and is provided with its own preamplifier. The disadvantage of this

Figure 5 Clinical receive-only volume coil. Reproduced by permission of Bruker Medical, Ettlingen, Germany.

approach is the relatively high price of the multiple amplifiers required.

Faraday Cage

The antennas used to detect NMR signals will pick up extraneous signals from the environment unless they are shielded in some way. In a high-resolution NMR instrument the bore of the magnet acts as a waveguide, effectively shielding the RF coil from the outside world. However, in imaging systems the dimensions of the magnet bore are often of the same order as the wavelength of the RF frequency of interest and then it is necessary to introduce additional shielding measures. The most common solution is to enclose the entire magnet in a continuous sheet or mesh of copper or aluminium. All services to this Faraday cage must be electrically filtered to ensure they do not act as gateways for environmental RF.

Quality Assurance

In addition to the physical hardware necessary to conduct an imaging experiment, every MR imaging lab will have a quality control process in place to identify spectrometer faults as they develop. In the clinical setting this will usually be included as part of the maintenance contract with the spectrometer manufacturer. Non-clinical labs will need to instigate their own procedures using standard samples called phantoms. The parameters that need to be monitored are signal uniformity (RF coil homogeneity), signal-to-noise ratio, geometric linearity, spatial resolution, slice thickness, and relaxation time.

Patient Monitoring

A description of ancillary equipment for the holding and positioning of animal and human patients is beyond the scope of this article. Similarly, monitoring equipment used for controlling animal or patient well-being such as pulse oximeters and blood pressure transducers will not be described. However, it is often necessary to monitor physiological parameters such as electrocardiogram (ECG) and/or respiration so that spectrometer acquisition can be synchronized with heart and/or abdominal motion. Many clinical systems have introduced optical transducers to convert the subject's ECG signal into optical signal for transfer via fibre optic lines to a monitoring device placed outside the magnet room. The advantage of the fibre optic line is that it cannot pick up extraneous RF and therefore does not need to be electrically filtered. Similarly, fibre optic and pneumatic devices are available for monitoring respiratory motion.

Computing

The same computers can be used for MRI applications as for high-resolution NMR. However, MRI systems can quickly generate large datasets requiring 2D and, these days, 3D Fourier transformations and, if there are animals or patients in the magnet, the operator will not want to wait for long periods during data reconstruction. Therefore, thought should be given to installing an adequate computer work-station to operate the spectrometer console. In addition, other workstations will be needed for off-line processing of images. The demands of multi-planar reformatting of 3D data, image segmentation, surgery planning and so on can also be quite intensive and so these additional machines also need to be high-end machines.

Safety

Magnetic Field

The static magnetic field of any NMR instrument poses a hazard to persons with surgical implants. The large bore and horizontal geometry of most MR superconducting scanners means that the stray field can emanate for several metres and provision must be made to prevent members of the public being exposed to a potentially lethal threat. Normally, this will consist of appropriate warning signs and restricted access to areas where the field is above 0.5 mT (5 gauss). However, in addition to the well-known dangers of static magnetic fields there is a potential hazard to patients and volunteers from peripheral nerve stimulation due to switched magnetic field gradients. This occurs when strong gradients are switched on very rapidly and results in muscular twitching and, possibly, pain. Clinical systems that can achieve such fast gradient switching should have a gradient supervision unit to ensure that they meet the requirements of the appropriate regulatory agencies, e.g. the Medical Devices Agency in the UK and the Food and Drug Administration in the US. The switching of magnetic field gradients also generates acoustic noise, which is a potential risk to both patients and staff.

RF

Pulse sequences that generate multiple 180° RF pulses can cause local tissue heating. Again the national regulatory agencies have laid down guidelines on RF power deposition in human subjects and an RF supervisor unit is necessary to ensure compliance.

Cryogenics

Superconducting magnets may contain hundreds of litres of liquid helium. In the event of either a spontaneous or

emergency quench of the main magnetic field, possibly due to someone being trapped against the magnet by an uncontrolled ferrous object, the energy stored in the superconducting coils of the magnet dumps into the cryogenic liquid. The expansion factor for liquid helium is 760:1 so a large amount of cryogen gas is released into the surrounding space in a very short time. Magnet manufacturers have designed their magnets to fail safe under these conditions. However, there is still the risk of asphyxiation as an opaque fog of helium and perhaps nitrogen gas replaces the air in the magnet room. All clinical systems and large bore animal scanners should be fitted with a quench vent to allow these gases to escape safely. In addition, clinical scanners will require an oxygen detector set to alarm should the oxygen level in the magnet room fall below safe levels.

Future Trends

In the last few years MR functional imaging, in which activated regions of the brain can be visualized, and MR angiography, which visualizes flowing blood, have had a considerable impact on the specifications demanded of MR scanners. Both techniques benefit from high field strength and both rely on speed and hence gradient amplitude and switching speed. Combined with the inexorable drift to bigger and better magnets and magnetic gradient coils, there has been a move in the research MR field to follow clinical colleagues in demanding robust, easy to use scanners. In the pharmaceutical industry and in university laboratories it is often necessary to train

relatively MR illiterate scientists and technicians in the routine operation of the scanner. Automated tuning, shimming and resonance frequency adjustment makes this task easier. The introduction of actively shielded magnets to the small bore end of the market will mean these systems can be installed on crowded sites and thus greatly expand the potential market. In short, the future looks bright for continued improvement and expansion in the MR scanner market.

Symbols

B_0	applied static magnetic field strength
G	gradient pulse (G_{read} , frequency encoding; G_{cod} , phase encoding; G_{sel} , selective)
k	reciprocal-space wave vector
q	wave vector
T	pulse duration
T_1	longitudinal (spin–lattice) relaxation time
T_2	transverse (spin–spin) relaxation time
t_e	echo time
γ	gyromagnetic ratio
δ	pulse duration
δr	voxel size
Δ	delay between pulses
ρ	surface relaxation strength (relaxation for the fluid owing to relaxation centres on the solid surface);
ω	resonance frequency

In recent years a large amount of basic and applied work on the application of NMR and MRI to the study of fluid distributions inside porous materials has appeared. With NMR one selectively observes one type of nucleus, by choosing the corresponding resonance frequency ω at a given static magnetic field intensity B_0 through the Larmor relationship

$$\omega = \gamma B_0 \quad [1]$$

where γ is the gyromagnetic ratio of the examined nucleus. The proton, which is abundantly available in both water and oil, is the nucleus most frequently observed. This means that in contrast to other noninvasive visualization techniques NMR directly probes the fluid (liquid or gas) phases within opaque porous matrices. At the same time, the unique feature of NMR is that the signal is sensitive to the physicochemical environment of the fluid. Thus, characterization of the porous material itself is also possible.

Apart from the NMR signal intensity, which is proportional to the transverse magnetization, the main quantities of interest are the relaxation times, T_1 (longitudinal) and T_2 (transverse). It is through the modification of the relaxation properties of the fluid inside the solid phase that one can obtain physicochemical information on the porous matrix such as pore size,

permeability or surface chemistry. Moreover, diffusion and flow, or more exactly fluid particle displacements, can be measured and visualized by NMR techniques using pulsed gradient techniques. The susceptibility contrast between the fluid and the solid phases, however, is usually very strong in rocks, and consequently a significant line-broadening is observed. Thus, spin-echo methods must be used, and in some cases more specialized solid-state methods are necessary.

From these principles, new instruments for the characterization of oil wells by NMR have been designed and are now routinely used to obtain rock porosity, water, oil and gas saturations, and other quantities of interest to the oil engineer. Applications have also appeared in other fields such as civil engineering (water in cement, bricks or clays), polymer engineering (solvent in solid polymers or polymer–polymer mixtures) or fluid mechanics. Specific methods or hardware are being developed for non-medical applications of MRI and they may in turn find their way back into the medical field in the future.

Relaxation Properties of Fluids in Rocks

Surface Effects

One usually observes faster relaxation rates for fluids inside a solid porous structure than for bulk fluids. This can be described as a surface relaxation effect, two or three fluid molecular layers having a specific relaxation rate much shorter than the bulk value. The origin of this shorter relaxation rate, for most mineral materials like rocks, is the presence of paramagnetic centres (usually iron). It is also considered that a reduction of molecular mobility or orientation could play a role. Whatever the origin of the surface relaxation, it can be shown that, under conditions of fast exchange, the relaxation rate measured for the fluid inside the pore space is proportional to the surface to volume ratio S/V , i.e. is inversely proportional to a characteristic pore size. The proportionality constant is the surface relaxation strength ρ characteristic of the solid–liquid pair under consideration; its order of magnitude for water in sandstone is $8 \times 10^{-4} \text{ cm s}^{-1}$.

However, in many materials, pore sizes range over several orders of magnitude (from nanometres to hundreds of micrometres), and the experimental relaxation curves present a strong deviation from a monoexponential

decay. A first approach is to use a stretched-exponential law to describe the relaxation curve, which has the advantage that a single relaxation parameter is obtained. Another approach is to calculate a relaxation time distribution from the relaxation curve by Laplace inversion; this is a mathematical task that presents some difficulties (the solution is not unique), but the inclusion of a regularization term, which is equivalent to favouring artificially smooth distributions, allows one to obtain reproducible results. With the assumption of fast exchange in each pore and slow exchange between different pores, the relaxation time distribution then gives the pore size distribution directly; this relationship is theoretically valid under the condition of uniformly distributed surface relaxation properties. The value of ρ must be obtained independently, usually by the use of mercury porosimetry.

Susceptibility Contrast

The surface mechanism affects both T_1 and T_2 . Another microscopic mechanism influences the apparent transverse relaxation and has important consequences in the methodology. This is the susceptibility difference between the fluid and the solid matrix. This difference creates an inhomogeneous magnetic field inside the fluid, and thus a broader line width. The main consequence is that it is almost always necessary to use spin-echo methods to observe fluids in a porous matrix.

Moreover, fluid molecular diffusion inside the field inhomogeneities causes decay of the transverse magnetization. The phenomenon cannot easily be described analytically, owing to the random character of molecular diffusion and the geometric complexity of porous media. Multi-echo sequences, such as CPMG (Carr Purcell Meiboon Gill), are employed to obtain the transverse relaxation curve, and it is considered that at interpulse spacing short enough (below 1 ms) and at low enough magnetic fields (below 0.2 T) the influence of field inhomogeneities is eliminated for many rock applications. One then recovers in liquids T_2 of the same order as T_1 within a factor 2 or so, that is to say equivalent physicochemical information. However, diffusion in gases being faster than in liquids, the apparent T_2 for gases in rocks can be shorter than for liquids. Because T_2 measurement times by CPMG are orders of magnitude faster than acquisition times for robust T_1 determinations, this method has become the standard protocol in oil well logging instruments.

Laboratory Applications

Methods

Standard Imaging Sequence

The standard imaging sequence is the two-dimensional Fourier transform (2D FT) spin echo sequence, as described in Figure 1. It consists of a spin echo in

Figure 1 The two-dimensional Fourier-transform spin echo NMR imaging sequence. A $\pi/2$ radiofrequency pulse flips the magnetization into the transverse plane, where it is refocused into a spin echo at the echo time t_e by a π refocusing pulse applied $t_e/2$ after the first pulse. Spatial encoding is obtained (1) by using a shaped $\pi/2$ pulse, and simultaneously applying a selective gradient pulse G_{sel} to define a slice within the object; (2) by applying two read gradient pulses so as to form a gradient echo in coincidence with the spin echo, and by sampling N_{read} data points within the time T_{read} in the presence of the gradient G_{read} ; (3) by repeating the acquisition for N_{cod} different gradient values applied during the time T_{cod} with a maximum amplitude G_{cod} . One then computes the two-dimensional Fourier transform of the resulting $N_{read} \times N_{cod}$ data points in order to obtain a two-dimensional image. The products $G_{read} \times T_{read}$ and $G_{cod} \times T_{cod}$ are chosen to achieve the desired resolution within the image plane (see text).

coincidence with a gradient echo; the frequency encoding or read gradient pulses G_{read} and the phase encoding gradient pulses G_{cod} encode two orthogonal spatial directions; slice selection is obtained by the application of the gradient G_{sel} along the third orthogonal direction. The resolution within the image plane, or the voxel size δr , is fixed by the maximum applied gradient intensity G , and by the time duration of the gradient pulse T , through

$$\delta r = \frac{2\pi}{k} \text{ with } k = \gamma GT \quad [2]$$

The wave vector k represents the maximum length explored in the reciprocal space of the image. With gradient intensities G in the 20–100 mT m⁻¹ range, k can be of order 10⁴–10⁵ m⁻¹, or equivalently δr can be a few hundred μ m. Use of longer pulse gradients has a limited efficacy for resolution improvement in the case of heterogeneous porous media with susceptibility broadening, corresponding to a short lifetime of the NMR signal.

Thus, δr is usually much larger than typical pore sizes in rocks. This also means that MRI will give images at a macroscopic scale of fluid distributions.

More Complex Imaging Sequences

The 2D FT sequence can be extended to three-dimensional imaging by using the phase encoding scheme instead of selection on the third axis. Chemical shift information can be extracted by adding a complementary chemical shift dimension; however, this procedure has rarely been used in practice for two main reasons: (1) four-dimensional data acquisition requires a prohibitive duration, and (2) the susceptibility effect spreads the spectra to the extent that the method is irrelevant in many practical situations. A more frequent approach is to extract 'water-only' and 'oil-only' images, with the simplification that the two chemical species are considered to give only single lines, and to use special protocols to eliminate local field inhomogeneities due to susceptibility as much as possible. This can be done only on rocks 'clean' enough and at magnetic field strengths above 1–2 T. Other relevant physicochemical information can be extracted by relaxation time imaging: the methods used are standard relaxation time measurement sequences combined with 2D FT or 3D FT imaging sequences.

Resolution: Choice of Magnetic Field, Different Methods

A usual rule in MRI is that a better resolution can be achieved at higher field intensity by an improvement of the signal-to-noise ratio. In the MRI of heterogeneous media, one must carefully examine the validity of that rule, since the spatial resolution is intrinsically limited by the line broadening due to the susceptibility contrast, which can be overcome only by increasing the gradient intensity. Since the susceptibility-induced field inhomogeneities are proportional to the magnetic field strength, the resolution achieved will be a compromise between the gradient intensity available from the instrument and the signal-to-noise ratio available. Orders of magnitude for the susceptibility internal gradients can be from 100 mT m^{-1} (pores of $100 \mu\text{m}$ in a 1 T field) up to a few T m^{-1} (pores of $1 \mu\text{m}$ in a 0.1 T field), comparable to or much higher than the gradients available on large-scale imaging systems.

Other methods, which are usually considered as solid-state MRI methods because of their ability to obtain signals from samples with very short transverse relaxation times, offer very interesting possibilities for the exploration of small samples with very high controlled gradients. The first method uses fast oscillating gradients to obtain echoes at very short echo time; the second uses large static gradients and is called the STRAFI (Stray Field Imaging) method. The latter, which uses the very high gradients available in the stray fields of

superconducting magnets (these can be as high as 10 to 100 T m^{-1}), probably offers the best possibility of going beyond the limit of large susceptibility gradients. However, these methods present the limitation that only objects of about 1 cm in size can be examined at the moment.

Laboratory Measurements

Porosity, Saturation

The NMR signal amplitude gives a fairly straightforward measurement of porosity or fluid saturation when only one liquid (water or oil) is present in the porous sample, via simple calibration procedures such as reference measurements on bulk fluids in similar conditions. The relative accuracy achieved is usually of the order of 1% or better. Even so, extrapolation to zero time to eliminate relaxation weighting can be a difficult task in some iron-rich materials.

In diphasic cases (oil plus water), two simple techniques for the measurement of saturation have been suggested and used for laboratory applications. The first is to add to water a paramagnetic tracer, which effectively 'kills' the water signal by shortening its relaxation time below the observable limit; then only the oil signal is available. The second technique is to use NMR signals from other nuclei, such as deuterium (D_2O replacing H_2O) or fluorine ^{19}F (a fluorinated oil replacing the normal oil); the latter nucleus presents the advantage of resonating at a frequency only 0.94 times lower than the proton frequency. Chemical shift ^1H imaging should be the first choice technique, of course, and examples of chemical shift-resolved images have been obtained in various laboratories, at fields of about 2 T, of sandstone or dolomite samples saturated with water and dodecane (Figure 2). However, as discussed above, this technique can work only at static magnetic fields high enough to produce resolved water and oil resonance spectra, and with reasonably 'clean' samples in which line broadening does not cause their overlap. In addition, as detailed below, the analysis of relaxation spectra has also proved to yield fruitful information.

Information Obtained from Relaxation Times

The different physicochemical phenomena that influence relaxation times should be taken into account with some care when examining NMR images. At the same time, they can be exploited as specific contrast mechanisms.

The general theoretical picture described above relating pore size distribution and relaxation time spectra works satisfactorily for solid materials of reasonably uniform surface chemistry, such as many model porous systems (glass bead or particle packs), and most sandstones. A number of laboratory studies have used it to

Figure 2 Chemical-shift imaging (CSI) in laboratory MRI of oil/water in rocks: time course CSI images of oil (upper line) displacement by water (lower line) in a Baker dolomite core sample, over 30 h, obtained at a 1.89 T magnetic field strength. The absolute intensities are not normalized from one image to the other, thus the change in the ratio of oil and water intensities with time (from left to right) is the meaningful parameter. The oil signal is initially (upper left) more intense, but a uniform decrease in the oil signal and increase in the water signal with time is observed. Reproduced with permission from Majors PD, Smith JL, Kovarik FS, and Fukushima E (1990) *Journal of Magnetic Resonance* 89: 470–478.

deduce pore size distributions from longitudinal or transverse decay curves in saturated porous systems. The fact that NMR and mercury porosimetry, which measure respectively the accessible surface and the throat dimensions, give comparable pore size distributions can be explained by the regular geometry of these systems. One should also mention that an empirical correlation between hydraulic permeability and some representative relaxation time value has been observed to be more or less satisfactory. In other rocks with more irregular geometry, the relationship between throats and pore dimensions does not hold systematically.

Changes in fluid arrangement with saturation have been followed, for example, in drying or centrifugation experiments. The displaced water tends to occupy smaller and smaller pores as its saturation decreases, and the corresponding relaxation time spectrum is generally observed to be displaced to lower values. Light oils present lower surface relaxation strengths than water in many rocks, presumably because of the natural water-wet character of the rocks. As in the drying experiments, saturation changes in immiscible situations (water plus oil) are most apparent on the water part of the relaxation spectrum, which tends to be displaced to lower values as water is displaced out, while the oil part is generally less affected.

Figure 3 Imaging of wettability contrast: images of water-saturated Fontainebleau sandstone samples of similar porosity (15%) and permeability, but with different surface treatments, obtained at a 0.1 T magnetic field strength. The right-hand sample is without treatment and naturally water-wet, and the left-hand sample was rendered oil-wet by chemical grafting of a silane chain. The image was acquired with a repetition time of 1 s, longer than the T_1 of the water-wet sample but shorter than the T_1 of the oil-wet sample; the resulting contrast due to different T_1 -weighting by a factor 2 is much higher than the image signal-to-noise. Reproduced with permission from Guillot G, Chardaire-Rivière C, Bobroff S, Le Roux A, Roussel JC, and Cuiec L (1994) *Magnetic Resonance Imaging* 12: 365.

Surface wettability also has an influence on the surface relaxation process: hydrophobic treatments of originally water-wet surfaces, by grafting of organic chains or by coating of surfactant layers, are known to increase the water-proton relaxation times. Images weighted in wettability have thus been obtained from T_1 -weighted images in water-saturated rocks with different surface treatments (Figure 3). Moreover in mixed saturation (water plus oil) states the microscopic fluid arrangement depends on the surface wettability, and modifies the contribution to surface relaxation. Thus, NMR indices of wettability have been suggested from the shift of the water part of the relaxation spectrum at variable saturation. These indices are reasonably correlated to more traditional measurements of wettability properties. Fluid arrangement with respect to the solid surface has also been observed to influence the transverse relaxation for the wetting fluid via the susceptibility effect: indeed, the wetting fluid is in the vicinity of both a solid interface and the interface with the other fluid, while for the nonwetting fluid susceptibility effects play a role only on one fluid–fluid interface.

Another example of NMR relaxation weighting is the MRI study of mud filtration by rocks. Mud suspensions are used in oil-well drilling and their invasion into

the surrounding rock is of importance for petroleum engineers. Water relaxation is faster in the presence of the mud particles, owing to their large surface area. Thus, the building of filtration cake has been followed quantitatively by MRI, as well as depth filtration of clay in natural rocks.

In many other potential application fields, the heterogeneous nature of the materials or their short transverse relaxation times cause similar difficulties in the collection of MRI images. Two strategies can be used. The first is to examine samples of realistic size (10–20 cm) at a moderate resolution, of the order of 1 mm, if T_2 values are long enough, typically longer than a few milliseconds: low-field equipment allows the collection of such images in many heterogeneous cases. When a finer resolution is necessary, other methods or specific equipment should be used.

For long enough transverse relaxation, images have been obtained by conventional liquid-state MRI sequences in different systems. From images of a solvent in a polymer matrix, quantitative measurements of solvent diffusion and possibly of matrix swelling have been performed in several systems, such as water–epoxy, water–nylon, methanol or chloroform–poly(methylmethacrylate). Elastomers are another example of samples with long enough T_2 and for which conventional MRI gives effective detailed information: the presence of voids in ill-cured elastomers is a spectacular source of contrast (corresponding to susceptibility defects), which can disappear with curing treatment. For building materials such as limestone and sandstone, the situation is comparable to that of oil-bearing rocks, and drying experiments have been monitored quantitatively. Similarly, the hardening of cement pastes is related quantitatively to the evolution of the water signal and of its longitudinal relaxation time (**Figure 4**).

For other samples, more solid-like or specific techniques should be used. Multipulse line-narrowing methods are well adapted to the case of solid polymers, such as adamantane, poly(methylmethacrylate) and polyacrylate. Fast gradient switching has been used to obtain one-dimensional images of water or solvent distribution in zeolite powders, with T_2 smaller than 1 ms. Moisture in building materials can cause spectacular damage and some groups have developed specific NMR instrumentation for moisture profile measurement at 1 mm resolution by point-to-point acquisition in bricks and mortars; these building materials are of very fine porosity and of an iron content (a few per cent) prohibitive for liquid NMR with conventional systems. But it is probably the STRAFI technique that will allow the finest resolution in solids to be achieved and that presents the highest efficiency for overcoming susceptibility broadening in heterogeneous materials.

Figure 4 Thickening of a white cement paste monitored by MRI: time evolution of 1D FT images of water in white cement obtained at 0.1 T over 4 h (curve a, 1 h; b, 2 h; c, 2.5 h; d, 4 h). The acquisition duration of each profile is a few seconds; the sharp peak on the right corresponds to a water reference sample; during cement thickening, this peak maintains the same intensity, while the signal from the cement paste decreases, corresponding to the progressive immobilization of water as solid hydrates and to the shortening of the remaining liquid water T_2 . Flow and Diffusion

Methods

The simplest and most straightforward method for flow imaging inside porous materials at a macroscopic scale is to use paramagnetic solutions, which act as contrast agents just as in clinical applications of MRI. More refined techniques have been used to study flow and diffusion. Their basis is generally the pulse field gradient-stimulated spin echo sequence. Susceptibility differences also create problems and can lead to an undervaluation of diffusion coefficients; multi-echo versions of this sequence derived from the CPMG echo train have been shown to compensate the susceptibility artefacts to a large extent.

Imaging of velocity is also possible at a macroscopic resolution. An appropriate gradient pulse pair causes a phase shift of the NMR signal. This phase shift is proportional to velocity (if all spins within each voxel move with the same velocity), via a controlled factor equal to the product of the wave vector q and the time delay Δ between the gradient pulses (see **Figure 5a**). One can combine this velocity encoding gradient with the imaging gradient pulses, so as to compute a velocity image from the phase-shift image.

Another interesting and powerful approach for obtaining detailed information on the flow field inside

Figure 5 Sequences using stimulated echoes for flow velocity imaging (a) and for the measurement of the displacement distribution function without imaging (b). The use of stimulated echoes often proves very convenient since the NMR signal can be observed for longer delays Δ , limited only by the T_1 value. The pair of gradient pulses, when exactly matched, produce no phase shift for nonmoving spins, and for moving spins they induce a phase shift $\Delta\phi$ equal to the product of the wavevector $q = \gamma G\delta$, by the displacement $(r(\Delta) - r(0))$. For a uniform velocity field v , $(r(\Delta) - r(0)) = \Delta v$ everywhere in space and v can be found from the phase-shift measurement at a given value of q (a). In more complex flow situations, the full displacement distribution can be obtained from a Fourier transform analysis of data acquired with incremented G , and thus q , values (b).

porous materials (without imaging) is to study the displacement distribution function, which can be obtained by Fourier transformation of the NMR signal acquired for incremented values of the wave vector q (Figure 5b). Of course it is also possible (but time-consuming) to make images of the displacement distribution. For these methods, the flow should be steady during the long data acquisition under the different gradient conditions, but this is a very realistic condition considering the low values of the Reynolds numbers normally encountered in the study of flow in porous media.

Results

Some groups have mapped fluid velocity inside water-filled rocks, either sandstone or limestone samples, using the phase-shift method. The measured velocities have the expected order of magnitude and some reasonable correlation with rock porosity has been observed. However, one should be aware that in these studies the spatial

Figure 6 Velocity probability distribution $P(v/\langle v \rangle)$ as a function of $v/\langle v \rangle$, where $\langle v \rangle$ is the average velocity, for water flowing in a glass bead pack. For short Δ (solid line), corresponding to a displacement $\Delta\langle v \rangle = 0.08d$, where d is the bead diameter, the distribution can be described by an exponential decay, in agreement with the expected Stokes behaviour; here $d = 800 \mu\text{m}$, and $\Delta = 19 \text{ ms}$. For long Δ (dashed line), corresponding to a displacement $\Delta\langle v \rangle = 7.3d$, the distribution can be described by a Gaussian law in agreement with the classical models of hydrodynamic dispersion in a porous media: here $d = 80 \mu\text{m}$, and $\Delta = 103 \text{ ms}$. Courtesy of Lebon L, Leblond J and Hulin J-P PMMH, CNRS UMR 7636, ES-PCI, Paris, France.

resolution is usually larger than the pore sizes, i.e. larger than the scale of velocity variations, so the measured phase shift is related to some velocity value averaged in a complex way over the microscopic velocity distribution, in both space and time.

Other groups have measured, without imaging, the displacement distribution function for water in bead packs, and for water and oil in sandstone, and have examined its dependence on the time delay Δ . At short Δ , or at a mean displacement smaller than the pore size, the displacement distribution corresponds to the velocity distribution and has an exponential shape, in good agreement with numerical simulations of Stokes flow. At long Δ , or for a mean displacement larger than a few pore sizes, the distributions have more a Gaussian shape that reflects the hydrodynamic dispersion of the fluid particles in the velocity field (Figure 6).

Oil Well Logging

Logging Tools

A new generation of logging tools for measurement in the severe conditions encountered in oil formations has appeared in recent years. This has been made possible by the use of permanent magnets, such as samarium-cobalt alloys with Curie temperatures above 200°C . The sample of

Figure 7 Example of an NMR logging tool sensor prototype working at 4 MHz. The main magnetic field is produced by permanent magnets, plus V-shaped polar pieces to concentrate the magnet induction in the central plane, so as to define the measurement zone in the central area, with a spatial resolution along the tool axis of 2 cm. As the tool moves along the bore wall, the spins are prepolarized by the magnet induction before they arrive in the measurement zone; thus the standard logging speed can be as high as 15 cm s^{-1} . One can see the V-shaped main polar pieces between two cobalt–samarium permanent magnets, the RF antenna in the V space and the tuning capacitor. Courtesy of Locatelli M. LETI CEA-Technologies Avancées DSYS, Grenoble, France.

interest is the rock formation surrounding the tool, in contrast to the usual laboratory NMR situation where the sample of interest is inside the magnet and the RF probe, and different designs for the static magnetic field and for the RF probe, adapted to this specific geometry, have been developed. Working static magnetic fields of 10–100 mT can be obtained, with sensitive volumes of toroidal shape that are typically of $20\text{--}1000 \text{ cm}^3$, at a distance of a few centimetres away from the borehole wall. From their specific designs, the static magnetic field for most logging tools is in fact a field gradient of about 100 mT m^{-1} . Another severe constraint is that the tool must move continuously in the bore, at speeds of several cm s^{-1} . Under these conditions, chemical shift is not observable, and the only NMR pulse sequence fit for use is the CPMG echo train. Typical logs consist of one-dimensional images (along the bore axis) of the NMR signal intensity and of the relaxation time distribution extracted from the CPMG measurement, at a resolution of about 0.2–1 m; from these data, rock porosity and various information on recoverable oil can be computed. **Figure 7** shows as an example a prototype logging tool that was designed to attain a finer spatial resolution of 2 cm.

Logging Applications

The NMR signal intensity provides a measurement of the fluid-filled porosity. However, water in clay or shale

has an apparent T_2 that is too short to be visible to the logging tools and the NMR signal comes mainly from water in larger pores and from oil. From the relaxation time distribution, an estimate of the movable fluid, called the free fluid index (FFI), is obtained by choosing a cutoff value, from *a priori* knowledge of the formation lithology. FFI is the proportion of fluid with relaxation times higher than this chosen value, or the proportion of fluid within pores larger than a given cutoff size. Laboratory measurements of centrifugeable water have shown a reasonable correlation with FFI measurements derived from NMR logs. An empirical estimate of permeability is also often calculated from FFI.

The differentiation of water from oil is based on the same general trends as presented above. The relaxation time spectrum can be separated into two parts: the water relaxation times are the shorter and change with the saturation state, whereas the light oils have the longer relaxation times, which are not strongly modified by confinement in the rock. It is also possible to detect the presence of gas, since at the high pressures in the reservoirs the corresponding density gives an NMR signal intensity only about 5 times lower than the signal from liquid oil or water. Gas can be distinguished from the other fluids through its specific relaxation behaviour: T_1 is a few seconds and T_2 is strongly influenced by diffusion effects in susceptibility-induced field inhomogeneities because of the higher diffusion coefficient of the gas. It has been shown that the amount of gas-filled

porosity can be measured from T_2 acquisitions differently weighted in diffusion by changing the interpulse spacing in the CPMG sequence.

Symbols

A_i	a measure of the extent of the object in the plane at r_i
B_0	applied magnetic field strength
$B_1(t)$	RF pulse profile
$B_1(w)$	field at sample due to unit current in coil
C	contrast
CNR	contrast-to-noise ratio
f	bandwidth
$f(f)$	frequency spectrum
G	gradient field amplitude
G_r	gradient field along r axis (parallel to z axis and to B_0)
h	Planck constant/ 2π
I	spin quantum number
k_B	Boltzmann constant
K	profile relating RF intensity and spectral content
l	receiver coil winding length
n	number of observation points
N	Avogadro number
P_i	proton density at position r_i
r_i	position along r axis
s	receiver coil winding circumference
S	signal strength
SNR	signal-to-noise ratio
t	observation time
t_p	RF pulse duration
T	temperature
TE	echo time
TR	time between successive excitations
T_1	spin-lattice relaxation constant
T_{2ijk}	spin-spin relaxation constant for ρ_{ijk}
T_p	duration of phase-encoding pulse
T_{ip}	duration of inverted gradient pulse
T_{ap}	half duration of acquisition gradient pulse
V	ample volume
ω_0	γB_0
W	width of slice
α	flip angle
γ	gyromagnetic ratio
μ	relative permeability
μ_0	permeability of free space
ξ	proximity factor
ρ	resistivity of coil material

ρ_{ijk}	proton density of the ijk voxel
ω	angular frequency

Introduction

In essence the theory of nuclear magnetic resonance peculiar to magnetic resonance imaging (MRI) alone is very simple and can be simply summarized as being a specialist application of multidimensional Fourier transformation NMR, in which the various frequency axes are related to spatial ones by assuming that the gradient magnetic fields applied to encode space produce equivalent frequency variations. In practice, the situation is very much more complicated, and involves reviewing a number of different aspects of the data recovery process.

In reality, the most complex differences between small-scale high-resolution studies and those involving human subjects lie not so much in the spatial encoding process but in the interactions between the RF coils and the subject and in the desirable targets for human studies. These are not, to anything like the same extent as in high-resolution studies, dictated by the need for quantitative accuracy of the measurement of a multiplicity of chemical components but are, rather, driven by the requirement to highlight certain structures of the body with respect to others. Imaging in general, and MRI in particular, is driven predominantly by issues of contrast. Whole-body magnetic resonance spectroscopy (MRS) is, similarly, driven by rather different factors from those affecting normal work in small-bore high-field spectrometers. In many ways MRS is closer to MRI in terms of its strategies and problems and both are, in effect, considered in this article (the former by implication only).

Relative to normal spectroscopy, both MRI and MRS rely to a very much greater extent on comparisons of results from regions of tissue considered to be normal and those felt to include more or less severely diseased structures. Biological diversity ensures that the reproducibility of results from one subject to another will not be as good as in most spectroscopic studies. On the other hand, much of what is attributed to this cause is due to ill-considered research strategies and artefactual results, but there is an undeniable level of difference between

individuals in animal species of all kinds so that the spread of results will always be greater than that obtained from small, passive samples. Sensate beings move in complex and more or less uncontrollable ways, have highly nonreproducible sizes and shapes and are hugely complex, so that practically all data obtained from them are contaminated by significant partial volume effects (which means that data sampled from a region of tissue contains components of multiple structures and a variety of different tissue types).

This article discusses the basic processes of spatial localization and the formation of images; it considers how the form of the signal-to-noise relationship is affected by the large, conducting load that the body represents, and how its movement affects the quality of the data obtained from studies. The issues surrounding the creation of contrast, which is the prime clinical desire of MRI strategies, are addressed in a separate article on contrast mechanisms (q.v.). This also discusses the development of a number of important artefacts, the formation of which is a derivation from the strategies outlined in this article. The reader may find it convenient to treat both as being closely related topics in *in vivo* NMR.

In all of what follows, it is assumed that the reader is familiar with conventional NMR theory as described elsewhere in this encyclopedia (see Further reading), as this article examines only the extensions needed to the theory and practice that are the basis of whole-body MR.

Spatial Localization

The basic concept of imaging is very simple. Gabillard first suggested the use of magnetic field gradients as a means of identifying positional data in NMR. However, it required the development of Fourier-transform NMR before these ideas could be usefully applied to imaging in its standard form. Mansfield and Grannell pioneered the application of gradients in FT-NMR, with the aim of achieving the analogue of optical diffraction, with resolution of lattice plane dimensions, while Lauterbur was the first to publish a two-dimensional image of an identifiable object.

In principle, assuming that B_0 is completely homogeneous, application of a gradient G_r (the component of a field varying along the r axis parallel to the Z axis (parallel to B_0)), results in a divergence of the spin resonant frequencies represented by

$$\omega_i = \gamma(B_0 + r_i G_r) \quad [1]$$

where $r_i G_r$ is the magnitude of the gradient field at position r_i along the gradient. If the object is multi-dimensional (as in the human body), the signal observed

at frequency ω_i (S_i) is derived from all the spins in the plane orthogonal to the gradient axis through r_i .

If we have a series of planes normal to r with respective uniform proton densities P_i at distances r_i (each generating a signal S_i) then, after demodulation, the signal from the whole object (S_{obj}) is given by

$$S_{\text{obj}} = \sum_{i=1}^n S_i = \sum_{i=1}^n A_i P_i \exp(-i\gamma r_i G_r t) \quad [2]$$

where A_i measures the extent of the object in the plane at r_i . In the limit, this becomes

$$S_{\text{obj}} = \int_r P_r A_r \exp(-i\gamma r G_r t) dr \quad [3]$$

ignoring all relaxation effects.

The above argument can be developed in two, or all three, dimensions to yield, for the latter, a relation of the form:

$$S = \int_x \int_y \int_z \rho_{ijk} \exp\left(-\frac{TE}{T_{2ijk}} + i\gamma TE(G_x x_i + G_y y_j + G_z z_k)\right) dx dy dz \quad [4]$$

where ρ_{ijk} is the proton density of the (ijk) voxel, and T_{2ijk} is its spin-spin relation time constant. This recognizes that there will be, at least, monoexponential transverse relaxation effects in the data, and that their magnitude will be those developed at a time TE (the echo time, the impact of which will be discussed later), which is the time at which it is assumed all spin dephasing due to the applied gradient is zero during the data acquisition.

In practice, the gradients require to be applied at different times to achieve the desired three-dimensional encoding, since the concurrent application of more than one gradient identifies a single axis, which is that determined by the vector sum of the applied fields.

Spatial Resolution

It is easier, at the beginning, to discuss how resolution is controlled by the spatial encoding process by considering a single-axis experiment (as in eqn [3]). In order to achieve a resolution of n points along the direction of observation, the Nyquist criterion demands that there is a $n/2$ Hz spread of frequencies across the field of view being studied. Thus, the gradient G_r , the distance r which spans the object, and time t for which the signal is observed are related by

$$n\pi = \gamma G_r r t \quad (\gamma \text{ in Hz/T}) \quad [5]$$

During the period t at least n data samples are required to identify the individual frequencies.

Conventionally, all imaging procedures acquire data in the presence of a gradient, depending on eqn [5]. In spatially localized spectroscopy, data are frequently measured in the absence of any gradient field and this approach could also, in theory, be useful in microscopy experiments, though in this case to minimize the impact of diffusion.

Essentially, there are only two fundamental imaging strategies, though with a growing number of variants of each. In one, the spins are excited and data are recovered along a direction determined by the vector sum of the applied gradients until enough has been collected, after which the magnetization is allowed to recover before it is excited again and data are acquired with a different gradient vector direction. The other strategy exploits the property that after excitation spins retain the phase relationships into which they have been placed by the application of a short pulsed gradient field. In a good field, the relationships are held sufficiently well as the system relaxes for another gradient to be applied for long enough, in what is usually an orthogonal direction, while data are recovered. Subsequently, after time for the magnetization to recover and be excited again, another, different, gradient pulse is applied and more data are obtained. The process is then repeated sufficiently often for a complete set of the information needed for a two-dimensional image to be obtained.

The former technique was that known as filtered back-projection, which, as originally applied, was a direct MR analogue of the original translate-rotate CT-X-ray scanner developed by Hounsfield. The first version of the other strategy, involving Fourier transformation in two or more directions, was proposed by Ernst and his colleagues in a form that ultimately proved much less useful than the spin warp method that has become the basis of the vast majority of clinical MRI.

The aim of every image recovery procedure is to obtain enough good information to fill all the locations of 'k-space' (i.e. spatial frequency space) so that when the data processing has been completed there are no artefacts in the image due to missing or corrupt data.

Figure 1 shows the sequence form (a,b) and coverage of k-space (C) developed during back-projection imaging. The various acquisitions form the spokes of a wheel and are produced in a plane (say the X/Y plane used as an example here) by the vector sums of the two gradients x ($= R \cos \theta$) and y ($= R \sin \theta$). Sufficient acquisitions are made to cover k-space at the density required. Suppose that the target of the image acquisition is an $n \times n$ matrix. The number of acquisitions needed to cover k-space is then $\pi n/2$. As will be discussed below, the efficiency of data acquisitions that fill k-space along orthogonal co-ordinates is better (as these require n acquisitions only) and this is one factor contributing to the unpopularity of back-projection acquisition.

It will be noted from **Figure 1** that if data were to be acquired as shown in **Figure 1a**, then regular sampling would result in oversampling at the start of the acquisition (as the spin frequency spectrum is spreading relatively slowly), though it may be just adequate later (after the gradients have flattened out and the full set of spin frequencies has developed). This form of acquisition was used in the early days of MRI by sampling the data nonlinearly (to account both for delays in amplifier response to command signals and for eddy currents arising from the changing gradients). Conjugate symmetry was also used to permit a significant reduction of the number of acquisitions as they only had to sample data though 180° .

Back-projection suffers from major problems in poor fields owing to those fields resulting, in effect, in the angular misplacement of points in k-space (which reconstruct to give streaks of intensity variation leaving the edges of structures). The centre of k-space is oversampled (and has an appropriately improved signal-to-noise ratio) as sampling can be continued as long as there is useful signal, though this results in angular undersampling at great distances from the centre. Nevertheless, the approach is not without merit. It is relatively impervious to the effects of motion (for reasons too complex to discuss in detail here) and it permits very high-resolution imaging of a local region in the body without the accompanying problem of aliasing that affects the spin warp method.

The spin warp technique and its development have, however, been the methods upon which practically all subsequent workers have based their work. The concept is shown in **Figure 2**. The block diagram of the data acquisition process is given in **Figure 2a** and the k-space strategy is indicated in **Figure 2b**. The data acquisition gradient is the same for each data recovery but the dotted lines indicate the varying nature of the phase-encoding pulses. The initial inverted gradient (G_i) (of the data acquisition) has the same value of

$$\int_0^{T_p} G_i dt$$

(where T_p is the width of the pulse) as the first half of the longer lower amplitude acquisition gradient (G_a) during the presence of which data are recovered.

Thus

$$\int_0^{T_p} G_i dt = \int_0^{T_{ap}} G_a dt \quad [6]$$

where T_p is the duration of the inverted gradient pulse and T_{ap} is half the duration of the acquisition gradient pulse.

Figure 1 Back-projection imaging. (a, b) Sequence form used for acquiring a back-projection data set for an image in the X-Y plane. At this time the slice selection procedure is simply shown as a block. It will be described later in the text. The X and Y gradients are constrained to define a series of vectors (given by $\theta = \tan^{-1}(Y/X)$ of constant magnitude $R (= (X^2 + Y^2)^{1/2})$: (a) shows the variant in the sequence used when conjugate symmetry is to be applied; (b) is the form of gradients used when an echo is to be formed during the flat regions of the gradients. (c) Coverage of k-space with back-projection. Workers reconstruct the data either using genuine back-projection algorithms (as in CT-X-ray) or by interpolating onto a two-dimensional grid, followed by a two-dimensional Fourier transformation.

During the warp gradient, spins are dephased, but they are then refocused at the centre of the data acquisition so that data sampling (which can be linear, as the gradient is constant throughout the data acquisition period) occurs through the echo peak. Thus, k-space is fully sampled for each line, and conjugate symmetry (as is needed for the technique in Figure 1a) is not necessary. The method is generally more robust than that in Figure 1, and in practice back-projection is also generally now implemented with echo formation (as in Figure 2b) except where it is desirable to acquire data as fast as is possible after excitation. The method in Figure 2a is a useful technique in the imaging of very short T_2 proton moieties or nuclei such as sodium that also have short T_2 values.

In order to cover k-space completely, all its lines must be filled. Each line is obtained using a 'phase encoding'

pulse (see Figure 2a), during which the spins precess at the frequencies dictated by the applied gradient. At the end of the gradient pulse, different groups of spins (isochromats) will have different phase relationships, which they retain in a perfect field along parallel lines even in the presence of another gradient applied orthogonal to the first. When enough phase-encoding pulses have been applied, each followed by a gradient in an orthogonal direction, the set of data generated will be given (ignoring relaxation and recovery effects) by

$$S_{x,y} = k \int_0^m \int_{-(n-1)}^n S_{p,t} \exp(i\gamma(xG_x t + p\Delta G_y T_p)) dp dt \quad [7]$$

where $S_{x,y}$ is the image dataset, assuming, in this case, that the readout direction is x, and the phase encode direction

y . ΔG_y is the increment in the y gradient between samples; T_p is the phase encode pulse duration. $S_{p,t}$ is the signal recovered at time t during recovery of the p th line of $J;k$ -space.

A two-dimensional Fourier transform applied to the data results in a set of amplitudes associated with the set of positions x, y .

The process can be extended to three dimensions by adding another phase-encoding step in the third orthogonal direction. This is altered after the complete set of phase-encode steps in the second direction has been obtained. In order to obtain sufficient data to generate a volume data set with $n_i \times n_j \times n_k$ voxels, $n_j \times n_k$ acquisitions of the n_i points in the readout direction are needed. If $n_j = n_k = 128$ (a relatively modest resolution target), 16 384 acquisitions are required. Even if the acquisitions are repeated at 20 ms intervals, the recovery of the data takes around 5.4 minutes. Extra time, to allow for

Figure 2 Spin warp imaging. (a) Sequence structure used in spin-warp imaging (again the slice selection component is shown as a block). The data acquisition gradient is fixed throughout the procedure; the phase encoding gradient is stepped uniformly from one extreme to the other, hence the difference from one excitation to the next. (b) The k -space average resulting from the spin-warp sequence.

greater recovery of signal after excitation, can quickly result in very extended, and practically unacceptable, durations. The signal-to-noise ratio in such imaging procedures can be very good, but the risk of patient movement, or even refusal to proceed, becomes much greater.

Slice Selection

In most instances, single planes of data ('slices') are recovered during imaging. Slice selection is performed by selective excitation, in which an RF pulse is applied at the same time as a gradient. This selects a slice orthogonal to the direction of that gradient.

The process is illustrated in **Figure 3**. The RF waveform is modulated by a computer-generated pulse profile to give a burst of RF frequencies that are as uniform in amplitude as possible and that have minimal components outside the bandwidth wanted. The pulse profile ($B_1(t)$) results in a frequency spectrum $f_{B_1}(t)$ which, in turn, results in a range of magnetization flip angles α_t given by

$$\alpha_t = \gamma K_{B_1} f_{B_1}(t) t_p \quad [8]$$

where K_{B_1} is a profile relating RF field intensity and the spectral content, and t_p is the pulse duration.

Even as the B_1 irradiation is present, and before the gradient is completely removed, the excited spins start dephasing relative to each other and, at the completion of

Figure 3 Slice selection process. (a) Envelope of the RF pulse (typical of the simpler pulses used). (b) Desirable burst of frequencies. (c) More typically achieved burst of pulses. The frequencies shown as negative are, of course, of opposite phase to those in the main block of frequencies. (d) Applied gradient with slice selected marked on it relative to the components of (a) to (c). The slice is shown as perfect, but actual performance is generally significantly poorer.

the process, little or no signal may be obtained. Another, inverted, gradient is then used to refocus the spins and reform the signal.

The width of the slice is determined by the gradient amplitude (G , conventionally measured in mTm^{-1}) and is given by

$$W = \frac{f_{B_1}(t)}{\gamma G} \quad [9]$$

Initially RF pulses such as sinc pulses (with trapezoidal gradients) or high-order sinc pulses (with sinusoidal gradients) were used. Now much more sophisticated complex pulses (i.e. containing real and imaginary profile information) are used to obtain better and more exact slice selection.

Because tissue relaxation times are relatively long, scanning times are typically quite extended, with much apparently wasted time. Crooks and his colleagues followed an earlier suggestion and showed how multiple slices could be interleaved between each other, and acquired at the same time, by varying the operating frequency of the machine at successive acquisitions. Coincidentally, they also showed how to exploit the relatively long T_2 relaxation time of many tissues to recover more than one image from each slice excitation.

Signal-to-Noise Ratio (SNR)

Although the basic formulation for signal-to-noise ratio is the same as in classic NMR, there are very significant differences in what actually happens. These arise from the fact that the body loading on the coils (which can generally be ignored in typical high-field (small-bore) systems) can easily dominate the noise from the resistance of the coils, and the input stages of the preamplifier, in all except very low main fields. The following discussion concentrates on factors that are important (or controllable) in the whole-body experiment. Thus we express Hoult and Richards' form for the signal-to-noise ratio, which is

$$\text{SNR} = \frac{N^2 \hbar^2 I(I+1) B_0^2 B_1(w) V s^{1/2}}{2(k_B T l \xi)^{1/2} (T \mu_0 \mu \omega \rho)^{1/4}} \quad [10]$$

where N is the Avogadro number, $\hbar$ is the Planck constant/ 2π , I is the spin quantum number, V is the volume of the sample, s is the circumference and l is the length of the windings of the receiver coil, k_B is the Boltzmann constant, T is the coil absolute temperature, ξ is the 'proximity factor' (dependent on things such as conductor spacing), ρ is the resistivity of the material of which the coil is made, μ is the relative permeability, $B_1(w)$ is the field at the sample due to a unit current

flowing in the coil ($\omega_0 = \gamma B_0$), as assuming only that field magnitude and coil design parameters are variables.

$$\text{SNR} \propto B_0^{7/4} B_1(w) \frac{s^{1/2}}{(l\xi)^{1/2}} \quad [11]$$

A unit volume is assumed as the target of the experiment. This derivation ignores any noise contributed by the object being studied, particularly one with large dimensions, and Hoult and Lauterbur later extended this formula to allow for the case where a large load is placed in the coil, to give the relationship

$$\text{SNR} \propto \frac{B_0^2}{\left(k_d \frac{n^2}{\theta} (\xi \rho \mu \mu B_0)^{1/2} (k_b + k_c \frac{g}{a}) + k_d B_0^2 b^5 n^2 \frac{\sigma}{a^2}\right)^{1/2}} \quad [12]$$

where the k_c etc. are numerical values. This describes the situation for a round 'headlike' object of radius b and conductivity σ in an n -turn saddle coil of included angle θ , radius a and length g .

The concept of the 'intrinsic SNR' was developed to demonstrate the sensitivity of system performance to changes in the main field in the situation where the coil is heavily loaded, giving it as

$$\text{SNR} \propto B_0 \quad [13]$$

in whole-body systems in which the body noise is the dominant factor (which it is in all except the lowest fields, or when the coils in use are very small or poorly coupled to the target tissue).

However, it was pointed out that in the form of data recovery generally used, in which multiple experiments are needed, relaxation effects cannot be ignored. Tissue T_2 is effectively constant over the range of fields used in current whole-body studies but T_1 shows a dependence on B_0 for which the empirical relationship [14] was proposed,

$$T_{1A} = T_{1B} \left(\frac{B_{0A}}{B_{0B}} \right)^v \quad [14]$$

where A and B are two field levels, and v is found, empirically, to be in the range of 0.3–0.4 for the majority of relevant tissues.

The signal in the most basic form of study is

$$S = S_0 \left[1 - \exp\left(-\frac{\text{TR}}{T_1}\right) \right] \exp\left(-\frac{\text{TE}}{T_2}\right) \quad [15]$$

where TR is the time between successive excitations, and TE is the time between the middle of the excitation RF pulse, and the time at which the central point of k -space is acquired. (The American College of Radiology published a glossary of terms for whole-body NMR quite

early in its clinical application. This ignored the traditional NMR notation quite cavalierly, but has become so well established in the biomedical community that it has been used in this article. Only in a few instances (some diffusion weighting and magnetization transfer terms) does it align with standard NMR practice.) Where TR is short relative to T_1 (as in volume scanning), eqn [15] reduces to

$$S = S_0^* \frac{TR}{T_1} = k S_0^* B_0^{-D} \quad [16]$$

where S_0^* includes the signal dependency on T_2 , and so on.

In addition, data have to be acquired over a finite period of time, as the acquisition gradient disperses the spin frequencies. Further, it is easier to recover data with a reduced bandwidth in lower fields as magnet homogeneities are conventionally expressed as fractions of the main field (and are a function of the unit design and relatively independent of field level), while dephasing effects due to field inhomogeneity are a function of actual field variations. For any one form of data acquisition, the noise voltage ($\propto f^{1/2}$, where f is the bandwidth of the acquisition) is proportional to $B_0^{1/2}$.

Taking into consideration these latter two factors, the overall signal-to-noise of a practical imaging experiment is

$$SNR \propto \left[1 - \exp\left(-\frac{TR}{T_1}\right) \right] (p B_0)^{1/2} \quad [17]$$

where p is the number of acquisitions needed to recover the data. Volume scans (where p can be very large) can thus have excellent SNRs, even if the acquisition time is long. At the extreme where $TR \ll T_1$, in a repetitive scanning situation,

$$SNR \propto B_0^{0.2} \quad [18]$$

(assuming $v = 0.3$) and the benefit of increasing the field is marginal. Note, however, that as TR increases, the performance at higher fields improves with respect to that at lower ones. In practice, in the majority of whole-body situations, where noise from the body dominates that from the coil and electronics, the limits of performance are set by artefacts.

Fast scanning, one of the most significant issues in imaging because extended scanning times are unpopular with patients, and uneconomic for hospitals, has followed two very different routes. In the first, a method much used for MR angiography and in volume acquisitions, short repetition times are used with a reduced flip-angle, selected using the relationship derived by Ernst and Anderson that relates flip angle (α), TR and T_1 for the

optimum signal-to-noise ratio:

$$\alpha = \cos^{-1} \left(\exp\left(-\frac{TR}{T_1}\right) \right) \quad [19]$$

This is clearly only ideal for any one tissue in a complex system with multiple T_1 values, but, in spite of reservations about its contrast, it has been applied very successfully.

The alternative strategies depend on acquiring many lines of k -space consequent upon a single excitation. Mansfield developed echo planar imaging very early on, to acquire whole images in a single acquisition, while other popular forms of fast acquisition of k -space data imaging are more modest in their ambitions. All pay some price in signal-to-noise ratio, but all have their uses and particular capabilities.

Imaging of solids (or other systems with very short T_2 or T_2^*) involves special techniques to overcome the need to encode spatial data very quickly. The approaches are not dissimilar to those of medical MRI, but the demands on the machine are more extreme, and the topic has developed a specialized scientific community of its own.

Contrast-to-Noise Ratio (CNR)

Clinicians who use MRI (and, indeed, in reality, all users who view MRI images as the basis of their studies) are actually less concerned about the signal-to-noise ratio of the data they have than they are about the contrast-to-noise ratio. In X-ray terms contrast is usually defined as

$$C = \frac{S_A - S_B}{S_A} \quad [20]$$

where S_A and S_B are the signals from two components A and B. In NMR this definition has proved inappropriate as S_A can be zero or nearly so, as can easily occur, for example, with the inversion recovery sequence (see below), which actually delivers very high contrast. For MRI purposes, contrast-to-noise is better defined as

$$CNR = \frac{S_A - S_B}{S_{0w} N} \quad [21]$$

where S_A and S_B are the signals as defined above, S_{0w} is the fully recovered signal from water (or other suitable reference) and N is the noise voltage. Much of medical MRI research has been devoted to studying how to maximize this ratio in a huge variety of diseases and circumstances.

Spectral Spatial Selectivity

It is not appropriate here to enter into a discussion of spectral spatial selection methods or their problems. However, it is worth making the point that these are much closer to the concepts (and difficulties) of MRI than they are to those of traditional high-resolution spectroscopy. In particular, problems of apparent low signal-to-noise ratio may have much more to do with artefacts than traditional noise. MRI has a surprising amount, largely ignored, to contribute to high-resolution spectroscopy.

Concluding Remarks

The implementation of spatial localization in MRI (or MRS) is not hugely complex, nor is it difficult in practice. In many ways, it is deceptively easy in both instances, and it is necessary to be very aware of the range of artefacts that can rise from inadequacies of very many kinds in the design of hardware, in its implementation and in its use. It is hard to overemphasize the need for stability and accuracy in the equipment used, nor to underrate the complexity and subtlety of the effects that can arise from failure to achieve these. Unfortunately, providing even a simple discussion of these is beyond the scope of this article, though there is a brief reference to them in another article on contrast mechanisms in MRI (q.v.). Almost invariably, except in very low fields, results from whole-body experiments are more determined by artefact than they are by noise. Not infrequently, the presence

of artefact is indicated only by an apparently excessive level of noise.

$T_{1\rho}$	relaxation time in the rotating frame
α	tip angle
γ	gyromagnetic ratio
τ	spin echo delay
ν	Larmor frequency
χ_g	magnetic susceptibility

Introduction

MRI is accomplished using gradients in the magnetic field flux density (normally referred to as the magnetic field). These gradients are generally produced in conventional imaging with the aid of sets of gradient coils. The suggestion to use the gradients that are present in the stray field of a superconducting magnet for imaging purposes was made first by Samoilenko and colleagues in 1988. The method has the advantage that these field gradients are large, of the order of 50 T m^{-1} . This has proved to be very useful not only for the imaging of solids but also additionally for the imaging of liquids in solids, neither of which can be imaged very satisfactorily or even at all with conventional MRI techniques. The method was generalized from one spatial dimension to three by Samoilenko and Zick, working at Bruker Spectrospin, but the technique was exemplified only by proton and fluorine work in diamagnetic solids such as organic polymers. The extension to multinuclear work, even quadrupolar nuclides, was accomplished by Randall and colleagues in one-dimensional studies. They also showed that the method gave good images of diamagnetic crystalline solids, and even of paramagnetic crystalline solids. Thus now virtually any nuclide, even those with electric quadrupole moments, can be imaged in any solid, with the possible exception of ferromagnetics. Because metals conduct electricity, they are not penetrated by radiofrequency fields and therefore can be imaged only

when in powder form. Distortions of the images produced by magnetic susceptibility are greatly reduced in proportion to the gradient strength.

The stray field and its large gradient have been of use for spectroscopic studies also, mainly for the investigation of relaxation times and of diffusion processes. Additionally, the basic spin physics in the stray field has been of considerable interest in its own right. In the case of quadrupolar nuclides, for example, solid-state NMR spectroscopy in the stray fields gives a new method of determining the electric quadrupolar coupling constant. This may now be scanned spatially for the first time.

Initially the acronym STRAFI was used to denote stray field imaging, but more recently it has been used by Randall and colleagues more generally to denote simply the stray field itself. Studies are not confined simply to imaging. The three types of work in the stray field may thus be referred to as STRAFI imaging (or STRAFI-MRI), STRAFI spectroscopy and STRAFI diffusion studies. All of these are covered in this article.

It is possible to combine the techniques and not only study *localized* free induction decays, relaxation times and self-diffusion coefficients but also construct maps of these properties.

The Stray Field

For superconducting magnets such as are used for NMR spectroscopy or for MRI studies, the central very homogenous field on the Z axis falls off rapidly as the distance from the centre of the magnet increases. Near the edge of the solenoid the gradient is particularly high. This is illustrated in **Figure 1**. The gradient can reach values of the order of $10\text{--}100 \text{ T m}^{-1}$ typically, depending on the value of the central magnetic flux density, the size of the bore of the magnet, and the details of primary coils. **Table 1** shows some typical values for proton resonance frequencies that have been reported for STRAFI work on various instruments: the positions in the gradient have not always been optimized.

Even higher fields are available on resistive magnets such as the 24 T magnet at the National High Magnetic Field Laboratory at the University of Florida. The maximum STRAFI gradient is approximately 138 T m^{-1} at a flux density of about 17 T corresponding to a proton

Figure 1 Plots of the field strength B_z on the Z axis versus distance x from the magnet centre (solid line, left-hand abscissa) and of the second derivative of B_z with respect to x (dotted line, right-hand abscissa). The plots are for a typical superconducting magnet (Magnex Scientific Ltd) of bore 89 mm and a centre field of 9.4 T. resonance frequency of 723 MHz. There is a 45 T system under construction.

High gradients give better spatial resolution in imaging experiments and allow the measurement of smaller diffusion constants. Additionally, they reduce the long-range effects of variations in magnetic susceptibility. Large fields are useful for the usual reasons, such as increased sensitivity, and for nuclides with low gyromagnetic ratios (γ) the higher resonance frequencies make probe ringing less of a problem. Thus the first solid-state STRAFI work on ^{14}N was accomplished at 32 MHz on the high-field, narrow-bore instrument shown in **Table 1**, in a stray field of 8.9 T.

So far no magnet has been designed specifically for STRAFI work. This is a development that can be forecast confidently since it should be possible to obviate the expense associated with very high central field

homogeneities. The exception is the portable system developed in Aachen by Professor Blümich's group called the MOUSE, which uses an asymmetrical permanent magnet and employs the field outside the magnet. There are analogies with the systems developed for oil-well logging: although the fields are very low the *ratio* of the field strength to the gradient strength is similar to values in work on conventional superconducting magnets.

The Spin Physics and STRAFI Spectroscopy

With gradients of the order of 50 T m^{-1} only a thin slice of the sample is excited for line widths of the order of a few kilohertz. The slice thickness for such narrow lines is governed (inversely) by the pulse duration, the value of γ , and the gradient strength. For 'isolated' protons in a 50 T m^{-1} gradient and a pulse duration of $10 \mu\text{s}$, the slice thickness is $80 \mu\text{m}$, which increases to $360 \mu\text{m}$ for ^{23}Na (even if the quadrupole coupling is zero).

For broader lines the line width of the sample in the absence of the gradient can become the governing factor. The line has, of course, two components, one due to homogenous broadening, governed by T_2 , and a heterogeneous component, say for polycrystalline samples, that depends on the dominant interaction (apart from the gradient): dipolar interactions for dipolar solids and anisotropic liquids; the quadrupolar interaction for quadrupolar cases; or even the chemical shift anisotropy.

The STRAFI free induction signal for a single pulse has a decay that is governed by T_2^* (T_2^* is the apparent T_2 including inhomogeneity effects) and diffusion. Since the large gradient makes T_2^* very short, it is usual to use the spin-echo technique of Hahn to overcome dead-time problems in the detection. The width of the echo is determined by T_2^* . The gradient term is negligible at the top of the echo where there is perfect refocusing. If diffusion is negligible then T_2 may be determined by arraying the spin echo delay (τ) since the echo relaxation is then governed by T_2 only. The STRAFI echo is a true Hahn echo even for solids (because the strength of the gradient dominates other terms in the Hamiltonian), so that any two pulses will in general give an echo irrespective of their relative phase. In the absence of the

Table 1 Typical values for the centre and stray fields and their proton resonance frequencies

Centre field (T)	Centre frequency (MHz)	Bore (mm)	STRAFI (T)	Fringe frequency (MHz)	Gradient (T m^{-1})
4.7	200	400	1.86	79	9.0
4.7	200	300	2.61	111	12.0
7.05	300	89	2.94	125	37.5
9.4	400	89	5.52	235	58.5
14.1	600	89	9.66	411	52.9
14.1	600	54	8.9	380	90.0
19.6	834	32	11.2	477	75.7

large gradient, dipolar solids will give an echo only if the relative phase is different: this is the dipolar echo.

STRAFI Hahn echoes are very useful spectroscopically since they are obtained for both solids and liquids even in the same sample. Additionally, multiple primary Hahn echoes from just two pulses can be produced in the stray field even from solids.

It is usual to employ a train of pulses to produce a train of echoes. These are not to be confused with the multiple echoes mentioned above. Application of more than two pulses gives both primary and stimulated echoes. For a pulse angle of 90° , the sample response is as shown in **Figure 2** both for the EVEN sequence, $90_x - [\tau - 90_x - \tau - \text{echo} -]_n$ which has no phase change, and for the ODD sequence, which has $90_x - [\tau - 90_y - \tau - \text{echo} -]_n$. The two sequences produce the same intensity for the first echo, the relaxation properties of which are determined only by T_2 , if diffusion is negligible. The echoes after the first one have more than one component, the number of which increases with the echo number. These contributions are all of the same sign for the ODD sequence, so that they augment each other – there is an analogy with constructive interference in diffraction – but not for the EVEN sequence, which produces echoes of opposite phase (destructive interference) and the up-down pattern shown in **Figure 2**. This has a (2 up, 2 down) pattern for 90° and an (n up, n down) pattern where n is an integer given by $180/\alpha$ when α , the pulse angle, is a submultiple of 180° . This is illustrated in **Figure 3**, which shows the responses for pulse angles of 60° (3 up and 3 down) and 45° (4 up and 4 down). The EVEN sequence is therefore very useful for the setting of the pulse angle. In fact, α varies across the slice but, remarkably, the observed value corresponds to the value at the middle of the slice, as confirmed by detailed calculations based on the Bloch approach or on the density matrix.

Figure 2 Plots of the calculated normalized echo intensity in the absence of relaxation and diffusion for the ODD sequence (top, circles) and the EVEN sequence (bottom, triangles) versus echo number following a train of 90° pulses. The first echo intensity is the same for each sequence and is governed only by T_2 in the absence of diffusion. Subsequent echoes have contributions from T_1 . The EVEN repeating pattern has two points up and two points down for 90° . Reproduced with permission from Bain AD and Randall EW (1996) Spin echoes in static gradients following a series of 90 degree pulses. *Journal of Magnetic Resonance* A123: 49–55.

The odd sequence has the advantage as in normal spectroscopy that it produces line narrowing if τ is short enough to produce some spin locking, in which case the T_2 contribution to the STRAFI-echo decay can be replaced by T_e (the effective decay time constant), which in the limit of spin locking may be approximated to $T_{1\rho}$. The line narrowing in the imaging experiments gives a greater spatial resolution. Even if there is no spin locking, extended echo trains may be produced since the last echoes

Figure 3 Experimental data of the EVEN sequence and a pulse angle of 45° , which gives a 4-up and 4-down repeating pattern, and 60° , which gives a 3-up and 3-down pattern. The signals were for ^1H at 237.5 MHz in the 58 T m^{-1} gradient of the Chemical Magnetics Infinity System at the University of Surrey for a silicone rubber sample. The τ value was $25 \mu\text{s}$. Reproduced with permission from Randall EW (1997) A convenient method for calibration of the pulse length in high field gradients using Hahn echoes. *Solid State NMR* 8: 179–183.

Figure 4 The echo decay for every third echo of 9000 ^2H echoes from a sample of heavy water in a gradient of 74.2 T m^{-1} and resonance frequency of 27.5 MHz . The tail of the decay is governed mainly by self-diffusion. The pulse duration was $4\text{ }\mu\text{s}$ (tip angle 90°). A total of 569 echo trains were accumulated with a repetition time of 0.5 s . Courtesy of Drs Teresa Nunes, Geneviève Guillot and the author.

have substantial contributions from T_1 . Very long values of T_1 and $T_{1\rho}$, and hence T_e , can be obtained in many aprotic solids particularly if a low- γ nuclide is being observed. A good example is ^{31}P in bone. In this case a very large number of pulses can be applied in a long pulse train which is of great advantage for signal accumulation (long echo train summation or LETS). The same behaviour can be seen even for quadrupolar nuclides; indeed the first such observation was for ^2H in heavy ice, for which 9000 echoes in each train have been produced. **Figure 4** shows the decay of the tops of these 9000 echoes. This decay is much longer than T_2 since echoes after the first have increasing degrees of T_1 governing their relaxation behaviour as the echo number increases. The decay is then said to be T_1 -weighted. Of particular interest is the case of ^{14}N , which for unprotonated nitrogens gives very long echo trains even when the value of the quadrupolar interaction is large, such as in sodium nitrite for which the literature value is about 4.9 MHz .

STRAFI spectroscopy resembles normal spectroscopy except that the chemical shift and dipolar interactions are too small to perturb the signal appreciably. Studies are therefore confined to the study of relaxation times and diffusion. For heterogeneous solid samples, or liquids in solids, discrimination between different motional components is possible, the contributions for components with fast motions being dominant for the last echoes in a long sequence.

For quadrupolar nuclides in solid samples that have a large electric quadrupole interaction, C_q , the echoes exhibit splittings and modulations that depend on the magnitude of C_q , which may thus be measured.

STRAFI-Diffusion

Gradients have been used for the determination of diffusion coefficients since the earliest days of NMR. The advantages of pulsed gradients led to studies using fixed gradients being superseded. Now, however, the STRAFI technique, which is a fixed-gradient technique, has the advantage of employing large gradients that bring into measurable range smaller diffusion constants. Kimmich and colleagues were thus able to measure diffusion coefficients as small as $6 \times 10^{-11}\text{ cm}^2\text{ s}^{-1}$ in siloxane melts at 20.5°C in a gradient of 38.4 T m^{-1} . Even smaller diffusion coefficients should be accessible at gradients higher than this.

STRAFI-MRI

STRAFI-MRI is a slice-selective method since even very short pulses excite only a narrow portion of the sample: Samoilenko's 'sensitive slice'.

The free induction decay of the excited slice contains spatial information, which can be revealed by Fourier transformation as in most other conventional NMR techniques. If the sample is a thin film with a thickness less than the width of the excited slice, the STRAFI image obtained in one spatial dimension is the image across the whole film. Larger samples, however, must be scanned to get the whole 1D projection. One way is to sweep the frequency of the pulse, but the older STRAFI method is to move the sample through the field. The first possibility is analogous to the method of frequency sweep in continuous-wave NMR spectroscopy. Field sweep in STRAFI-MRI has also been tried.

If the scanning is accomplished by sample movement, Fourier transformation is not necessary: the magnetization and the signal are directly proportional to the nuclear spin density. The 1D profile is generally obtained by translation of the sample along the Z axis of the magnet. The motion can be continuous, if it is slow enough, or stepwise. The size of the step may become the major factor governing the spatial resolution if it is coarse. The slices may be interleaved so that there is no interference between the excitations of contiguous slices. Accumulation can be accomplished by repeating the motion from the starting position, since this allows relaxation to occur during the recycle time of the motion. An alternative for samples with a long T_1 is to use very long pulse trains as in the ^{31}P example (the LETS protocol); see **Figure 5**.

The profiling can be repeated for different orientations around the same axis by rotation of the sample to produce a 2D image. Then the third dimension can be scanned by a second rotation orthogonal to the first. Back-projection algorithms can be used to produce the

Figure 5 ^{31}P one-dimensional (semi-elliptical) profiles of a cylindrical sample containing ammonium hexafluorophosphate. At each position four summed echo trains are shown for long echo train summation (LETS). The highest intensity is for $n=8192$ echoes. The gain in the signal-to-noise ratio is proportional to $n^{0.5}$, where n is the number of echoes in the train. The variation in n from the lowest to the highest intensity was 1024, 2048, 4096 and 8192. The odd sequence was used. Experimental details were resonance frequency 91 MHz; gradient strength 58 T m^{-1} ; τ value $20\text{ }\mu\text{s}$; pulse duration $3.6\text{ }\mu\text{s}$; manual steps 0.35 mm ; 64 averages of each echo train were used at 5.7 min per slice. Courtesy of Drs Duncan G. Gillies and Ben Newling.

images. 3D work is very time-consuming by this method, since there are not the usual gains from the Fourier technique, but it is possible with axially symmetric samples to design the sample (normally called the phantom in imaging studies) so that useful but short experiments can be conducted in one dimension only. Examples are liquids diffusing into solids, such as solvents into organic polymers (**Figure 6**), or water diffusing into cements or concrete (**Figure 7**). In each case, relaxation weighting can be used to advantage. The system shown in **Figure 6** depicts the diffusion of hexafluorobenzene into the polymer from right to left. The sensitive planes for ^1H and ^{19}F are displaced one from the other because of the different values for the gyromagnetic ratios, and so are the images. The separation between the planes is about 4.9 mm in this example. The overall image therefore has a proton region (at the left) and a fluorine region at the right. In the sample these two regions overlap. There is a direct analogy with the chemical shift effect in conventional imaging.

The best position in the stray field is actually not where the gradient is maximum, because at this position the resonant slice is not planar since the magnetic field off-axis is not uniform. The optimum position is where the slice is planar. This occurs where the lines of equipotential lines are orthogonal to the Z axis. Nearer the centre of the magnet the equipotential lines are curved one way, but further from the centre they curve another way. Exactly at the optimum position a flat disc extends

Figure 6 Profiles of a cylindrical phantom (5 mm thick, diameter 10 mm) of a polymer consisting of a 2:1 mixture of poly(methyl methacrylate) and poly(*n*-butyl methacrylate) following ingress of hexafluorobenzene (from the right): (a) projection produced from the first four echoes of 32 echoes; (b) projections from the last four echoes. The ^{19}F image is spatially separated at the right from the ^1H image at the left. The fluorine images exhibit spatially variable relaxation behaviour. The gradient strength was 37.5 T m^{-1} and the resonance frequency was 123.4 MHz . Reproduced with permission from Randall EW, Samoilenko AA, and Nunes T (1996) Simultaneous ^1H and ^{19}F stray field imaging in solids and liquids. *Journal of Magnetic Resonance* A117: 317–319.

somewhat off-axis, typically about 1 cm for superconducting magnets with bores of 8.9 cm .

The distortion of this disc away from the optimum position is not large for small samples, which are normally cylinders about $1\text{--}2\text{ cm}$ long and less than 1 cm in diameter, so that positions away from the optimum are frequently used. This is part of the reason for the apparent irregularities in **Table 1**. Thus, the inserts, RF channels and tuning boxes used for the study of ^{31}P in the central field may be used for protons in the stray field at a frequency that is rather lower than the optimum.

The gradient at the chosen position can be calibrated by measurement of an accurately known diffusion constant.

The spatial resolution has reached about $5\text{ }\mu\text{m}$ for ^1H in the case of line narrowing by spin locking for thin samples by use of the Fourier technique in a gradient of about 38 T m^{-1} in a 7 T magnet. For similar samples at the higher gradient strengths available on higher-field magnets, it should be possible to obtain a resolution of about $1\text{ }\mu\text{m}$. Typically, however, for protons the resolution is about $50\text{ }\mu\text{m}$ or less.

For the ^1H and ^{19}F nuclides, the sensitive planes are spatially separated, with the fluorine-sensitive plane being at higher field close to the magnetic centre. The distance between these planes depends on both the field and the gradient but can be of the order of 5 mm . This means that both the ^1H and ^{19}F signal of a fluorohydrocarbon can be detected as the sample moves. For a small

Figure 7 Hydration and curing of a Portland (type I) cement contained in a glass tube and covered with water without initial mixing of the components. The ^1H profiles were taken at various intervals thereafter: the top profile after 15 min; and the bottom one after 48 h. The peak at the right is from a plastic reference disc at the bottom of the vial, whereas the sharp peak at the left is from a parafilm top-cover and from water that initially condensed on it. The apparent loss of signal arises because of the growth of components with very short relaxation times as hardening occurs, which become invisible with the long echo times used ($\tau = 30 \mu\text{s}$). The resonance frequency was 123.4 MHz and the gradient strength was 37.5 T m^{-1} . The ODD sequence was employed with trains of 64 echoes; 50 echo trains were accumulated for each point on each profile with a repetition time of 1 s. Courtesy of Dr Teresa Nunes.

enough sample, for which the projection on the field axis is less than 5 mm, the two 1D profiles are completely separated, see **Figure 6**. This γ -displacement, similar to the chemical shift displacement in conventional imaging (which is too small generally to be seen with STRAFI work), is useful, otherwise the discrimination would have to be made with relaxation weighting alone. The γ -displacement itself can, however, be very small, so that

Table 2 STRAFI-frequencies of some nuclei in the 2.9 T stray field of a Bruker MSL 300 spectrometer and the proportion of the signal in the central transition

Nucleus	I	Frequency (MHz)	Intensity of central transition (%) ^a
^1H	$\frac{1}{2}$	123.4	100
^{19}F	$\frac{1}{2}$	116.1	100
^7Li	$\frac{3}{2}$	47.8	40
^{11}B	$\frac{3}{2}$	39.6	40
^{23}Na	$\frac{3}{2}$	32.2	40
^{65}Cu	$\frac{3}{2}$	32.2	40
^{27}Al	$\frac{5}{2}$	32.3	40
^{51}V	$\frac{7}{2}$	32.5	19
^{59}Co	$\frac{7}{2}$	29.2	19
^{115}In	$\frac{9}{2}$	27.0	15

^a The intensity of the central transition expressed as a percentage of the whole signal.

overlap nearly always occurs for certain pairs of nuclides such as ^{23}Na and ^{27}Al , ^{63}Cu and ^{65}Cu and ^{75}As and ^{115}In (see **Table 2**).

For quadrupolar nuclides of half-integral spin there is a relatively narrow transition ($\frac{1}{2}$ to $-\frac{1}{2}$) and much wider transitions for the satellites. It can be that, as in spectroscopy, the latter are effectively not detected. In this case the image is reduced in intensity by an amount that depends on the spin quantum number as shown in **Table 2**. The resolution then is determined by the line width of the central transition, which to first order is given by C_q^2/ν , where ν is the Larmor frequency. This can be of the order of kHz, so that the resolution is about the same as for dipolar-broadened ^1H in polymers, say. Curiously, if the signal-to-noise ratio increases, so that the satellite transitions are detected, the spatial resolution decreases.

It is possible to distinguish the loss of signal from this source from the case of a lower spin density by a comparison of the echo trains produced by the odd and even pulse sequences.

In the case of nuclides with integral values of the spin quantum number, there is no narrow transition and the slice thickness will be very large if the line width is big because of a large value for C_q . Thus the observed spatial resolution may be a factor of 10 worse than the correct image: a feature of a millimetre in the phantom may appear to be a centimetre or more in the image. This has been illustrated for ^{14}N in a series of samples in which the value of C_q was changed from 0 to about 5 MHz.

It can be noted here that an observed profile, O , is the convolution of the actual physical profile, P , and the line shape function L :

$$O = L \otimes P \quad [1]$$

Table 3 Some values of proton relaxation times in paramagnetic compounds and values of the gram magnetic susceptibility χ_g

Formula ^a	$10^6 \chi_g$	T_1/ms	$T_2/\mu s$
Eu(fod) ³	3.91	277	25.3
Dy(fod) ³	42.80	5.04	13.1
Ho(fod) ³	35.06	5.40	14.0
Yb(fod) ³	7.81	16.8	26.5

^a fod is the 6,6-,7,7-,8,8,8-heptafluoro-2,2-dimethyl-3,5-octane-dionato ligand.

If L is known, say for a powdered sample consisting of one component containing a known dipolar or quadrupolar interaction, from which the line shape can be computed, this source of heterogeneous broadening may be removed from the observed image by deconvolution. The resolution of the image is then determined partly by the homogenous broadening only, which is governed by T_2 or $T_{1\rho}$ if there is spin locking and line narrowing.

Samples that are paramagnetic have proved to be easy to image, at room temperature at least, rather surprisingly perhaps for high-resolution spectroscopists. The reason, as shown as long ago as 1950 by Bloembergen, is that the electron relaxation times are so short that the NMR line widths are not greatly affected. For $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ the proton line widths are determined mainly by the proton-proton dipolar interaction, and therefore the imaging problem is no different from that for a diamagnetic hydrate. The same holds true for other ligands and for more paramagnetic samples. An advantage is that although T_2 is not greatly affected, T_1 is shortened considerably, as illustrated in **Table 3**, which is an aid to accumulation when short pulse-trains are employed.

The compounds in **Table 3** have produced 1D profiles for both the ^1H and ^{19}F nuclides.

A most striking result is the observation of STRAFI echoes for the quadrupolar ^{51}V ($I = \frac{7}{2}$) nuclide in the paramagnetic vanadyl bis(acetonato) compound, which has two unpaired electrons on each vanadium atom. This result opens up the prospects of imaging for quadrupolar nuclides in paramagnetic situations in general.

Conclusions: Prospects for the Future

It is possible that STRAFI-MRI will become the method of choice for the imaging of solids, and samples consisting of solids and liquids. Any type of nucleus may be used, including quadrupolar nuclides, in any type of solid. All types of materials may be addressed. The method will be seen to best advantage when simple 1D profiles are sufficient for the particular study. Its worth has been shown already for water in cements (**Figure 7**) and concrete and other building materials, and for organic liquids in polymers, for which it has the advantage of imaging the

Figure 8 One-dimensional ^1H profiles for poly(vinyl chloride) polymer exposed at the left to acetone vapour of different activities for 48 h at 20°C . In (a) the circles are for an activity of 0.13, squares for 0.35, triangles for 0.60; and crosses for 0.82. The image of the largely undisturbed solid polymer is to the right. At the left the image has overlapping images of the ingressing acetone and the softening polymer. Part (b) shows the points for an activity of 0.35 in more detail, and those for an activity of 0.13 are shown in (c). The macroscopic diffusion in (c) is of case I type. The onset of case II diffusion at the higher activities is shown clearly in (b) and in (a) – the acetone in this case has a very sharp front that is absent in the case 1 example. STRAFI-MRI has the advantage that all components, solids as well as the liquid, can be imaged simultaneously. It is then possible to employ relaxation weighting to separate the components of the image. Reproduced with permission from Perry KL, McDonald PJ, Randall EW, and Zick K (1994) Stray-field magnetic resonance imaging of the diffusion of acetone into poly(vinylchloride). *Polymer* 35: 2744–2748.

undisturbed polymer, the softening polymer and the liquid phase in the softened polymer as illustrated in **Figure 8**. The macroscopic diffusion may be followed easily.

STRAFI-diffusion studies of microscopic diffusion can bring into range very slow self-diffusion coefficients.

STRAFI-spectroscopy in the excited slice can yield details of the relaxation characteristics in general, and even the values of C_q for quadrupolar nuclides.

These various techniques may be combined for spatial mapping purposes, e.g. for relaxation times and quadrupole coupling constants.

There seems to be little doubt that STRAFI studies will be of great value in the general field of materials science.

As regards clinical work, *in vitro* studies have proved to be very valuable: for example, the study of materials and cements for dental work and hip-joint prostheses. One may predict that *in vivo* studies will emerge. Indeed, having the subject nearly outside the magnet has considerable advantages. For human patients, the question of the safety aspects of the large gradients will need to be addressed.

It is likely that special spectrometers will be designed exclusively for STRAFI studies.

Introduction

In magnetic resonance imaging (MRI), the nuclear magnetic resonance (NMR) signal is spatially encoded to obtain images based on the local density of a spin-carrying nucleus. The discovery of MRI has led to a revolution in medical diagnosis, yet the same methods are used in a large number of nonmedical applications, for example, quality control of foodstuff, spatially resolved monitoring of chemical reactions, development of composite materials with novel properties, noninvasive analysis of the state of cultural heritage specimens, or geological surveys. One of the core features that distinguishes MRI from optical imaging techniques is the possibility to image the interior of optically opaque objects, as long as they have a low electrical conductivity and the electromagnetic radio frequency (rf) radiation resonant with the investigated spins can penetrate the material. MRI techniques designed for very high spatial resolution below approximately 100 μm , which cannot be resolved by the naked human eye, are termed magnetic resonance microscopy (MRM). Differences between MRM and MRI are based on the limited size of the samples used in MRM that makes it possible to accommodate them in the restricted space of magnets with very high magnetic fields (up to 19 T in commercial MRM systems), using very strong magnetic field gradients for spatial encoding. Furthermore, smaller samples allow for more sensitive antenna structures (the rf coils) used to excite and detect the NMR signal. Maximum resolution in MRM is often achieved by signal averaging over many hours, which is not practical in clinical

applications. However, the boundary between MRI and MRM is becoming somewhat blurred, since with the advent of high-field (7 T) whole body scanners, high spatial resolution has also become feasible for human MRI.

In this article, first a brief introduction to the theory of MRM is given. Then the basic techniques and tools to obtain high spatial resolution in magnetic resonance experiments are summarized. The next section discusses that in addition to the spin density, other means of contrast, such as the chemical shift of different species in a sample, the diffusion coefficient, or the relaxation times, can be used to enhance the information content in MRM. Finally, some examples are given to illustrate the broad range of applications MRM can be used for.

Principles of Image Acquisition

The signal acquired in NMR arises from the Zeeman effect when nuclei carrying a nonzero spin are placed in a magnetic field. Nuclei with a spin quantum number of 1/2, such as ^1H , ^{13}C , or ^{31}P , can occupy one of two possible quantum states. When placed in a strong external magnetic field, $\mathbf{B}_0$ (whose magnitude is B_0 and whose direction is conventionally assumed to be along the laboratory z -axis), a weak sample magnetization, $\mathbf{M}$, aligned with $\mathbf{B}_0$ arises from a small difference in spin populations of these two quantum states. $\mathbf{M}$ can be manipulated by application of resonant rf pulses. These pulses are commonly characterized by the flip angle that $\mathbf{M}$ is rotated away from its initial orientation. A $\pi/2$ pulse applied to the equilibrium sample magnetization $\mathbf{M}_0$, for instance, transfers the whole magnetization into a plane orthogonal to $\mathbf{B}_0$, where it precesses at a rate characteristic for each type of nucleus. At the heart of spatially resolved NMR imaging experiments lays the simple proportionality relation between the angular precession frequency ω (the Larmor frequency) of the sample magnetization and the strength of the magnetic field to which the sample is exposed,

$$\omega = -\gamma B_0 \quad [1]$$

The constant of proportionality, the gyromagnetic ratio γ (with units of $\text{rad s}^{-1} \text{T}^{-1}$), depends on the type of nucleus detected in an NMR experiment. The proton is frequently the prime candidate for MRM because it has a high value of γ relative to most other nuclei and because of the high natural abundance of ^1H in many materials, particularly in water.

To obtain a signal that contains information about the geometry of a sample, the magnetic field is made spatially varying by applying a linear magnetic field gradient, $\mathbf{G}$ (with units of T m^{-1}), across the sample. Consequently, the Larmor frequency becomes a function of the space vector $\mathbf{r} = \{x, y, z\}$

$$\omega(\mathbf{r}) = -\gamma(B_0 + \mathbf{G} \cdot \mathbf{r}) \quad [2]$$

The effect of the gradient $\mathbf{G} = \{\partial B_z/\partial x, \partial B_z/\partial y, \partial B_z/\partial z\}$ is to encode spatial positions of nuclear spins into frequency components of the NMR signal. Technically, this is implemented by three orthogonal gradient coils, each of which can be driven independently. The signal of each frequency component is proportional to the spin density $\rho(\mathbf{r})$ of the sample at the corresponding position $\mathbf{r}$, which is the quantity one seeks to represent in the MRM image. Neglecting, for the moment, relaxation processes that may affect the intensity of the NMR signal, the acquired time-domain signal can be expressed as

$$S(t) = \int \rho(\mathbf{r}) \exp[i\omega(\mathbf{r})t] dV \quad [3]$$

where the integral is over the three-dimensional space comprising the sample, and dV is the infinitesimal volume element. The NMR signal is usually recorded relative to a reference signal at frequency $-\gamma B_0$ in heterodyne detection mode; therefore eqn [3] can be written in a frame of reference rotating with the carrier frequency as

$$S(t) = \int \rho(\mathbf{r}) \exp[-i\gamma \mathbf{G} \cdot \mathbf{r}t] dV \quad [4]$$

Using the reciprocal space vector $\mathbf{k} = \gamma \mathbf{G}t/2\pi$, eqn [4] becomes

$$S(\mathbf{k}) = \int \rho(\mathbf{r}) \exp[-i2\pi \mathbf{k} \cdot \mathbf{r}] dV \quad [5]$$

The spin density can be obtained by inverse Fourier transform of $S(\mathbf{k})$,

$$\rho(\mathbf{r}) = \int S(\mathbf{k}) \exp[i2\pi \mathbf{k} \cdot \mathbf{r}] d\mathbf{k} \quad [6]$$

where $d\mathbf{k}$ is the infinitesimal element of the three-dimensional k -space.

In an imaging experiment, k -space is sampled by incrementing the $\mathbf{k}$ vector in linear steps of $\Delta \mathbf{k}$. The three orthogonal magnetic field gradients must be sampled independently to distinguish different locations in all three spatial dimensions. However, if only a planar image through the sample is required instead of a full three-dimensional representation, it is sufficient to excite nuclei in a thin 'slice' by band-selective rf pulses in the presence of a magnetic field gradient, followed by the

application of two additional orthogonal gradients to encode the signal in the two remaining spatial dimensions. Since $\mathbf{k}$ depends on both the amplitude and the duration of the gradient, two different strategies can be used to increment $\mathbf{k}$. In the first strategy, termed *frequency encoding*, the signal is transiently sampled in steps of Δt by acquiring N sample points during a free induction decay (FID) or an echo while a gradient is applied. Alternatively, the spin ensemble of the sample can be consecutively excited N times, each time acquiring an FID or echo after the application of a gradient whose amplitude is incremented in steps of $\Delta \mathbf{G}$. In this strategy, termed *phase encoding*, the phase of the signal is modulated depending on the gradient amplitude applied before detection. In spin-warp imaging (see **Figure 1(a)**) these two strategies are combined. Alternative sampling

Figure 1 Rf and gradient pulse sequence building blocks commonly used for MRM. (a) Image recording sequence. In this example, a slice in the x dimension is selected by applying a selective rf pulse in the presence of a magnetic field gradient. Phase encoding is performed along y , where the intensity of the gradient is stepped through different values. Frequency encoding is performed along z , where first the magnetization is dephased with a gradient, and then a gradient echo is recorded after the π pulse during the acquisition time T_{aq} . (b) PGSE sequence to encode molecular motion. Two identical gradients are applied, with a π pulse in between. The second gradient pulse reverses the effect of the first for spins that did not change their location during Δ . Coherent motion leads to the accumulation of an additional phase, while diffusion causes an echo attenuation.

strategies have been reported with radial sampling of the k -space in conjunction with back projection. This offers signal-to-noise advantages when materials with short transverse relaxation time constants are studied.

The field-of-view (FOV) in real space of the MRM experiment is given by $\text{FOV}_\alpha = |\Delta k_\alpha|^{-1}$, where α represents the x , y or z direction. For frequency encoding

$$\text{FOV}_\alpha^{\text{fe}} = \frac{2\pi}{|\gamma G_\alpha \Delta t|} \quad [7a]$$

and for phase encoding

$$\text{FOV}_\alpha^{\text{pe}} = \frac{2\pi}{|\gamma \Delta G_\alpha t_x|} \quad [7b]$$

where t_x is the duration of the gradient pulse whose amplitude is varied from $G_\alpha^{\min}$ to $G_\alpha^{\max}$ in steps of ΔG_α . The nominal spatial resolution, $\Delta r_\alpha = \text{FOV}_\alpha / N_\alpha$, of the MRM image depends on the number N_α of increments Δk_α . Along dimension α thus

$$\Delta r_\alpha^{\text{fe}} = \frac{2\pi}{|\gamma G_\alpha T_{\text{aq}}|} \quad [8a]$$

is obtained for frequency encoding, where $T_{\text{aq}} = N_\alpha \Delta t$ is the acquisition time, and

$$\Delta r_\alpha^{\text{pe}} = \frac{2\pi}{|\gamma (G_\alpha^{\max} - G_\alpha^{\min}) t_x|} \quad [8b]$$

for phase encoding.

In general, the major problem to overcome for increasing the spatial resolution in MRM is the diminishing signal-to-noise ratio (SNR), since the signal is proportional to the voxel volume and therefore decreases with the third power of the spatial resolution, assuming an isotropic voxel size. The SNR problem can only partly be eliminated using magnets with very high fields and optimized rf coils. Furthermore, in the previous considerations NMR signal attenuation due to relaxation mechanisms and diffusion processes were entirely neglected. Particularly in MRM, these processes play a crucial role in limiting the achievable spatial resolution. Frequently, the signal dephasing time constant T_2^* , which characterizes the exponential function of the FID or the echo, is on the order of only a few milliseconds. The achievable spatial resolution with frequency encoding is, under such circumstances, limited to

$$\Delta r_\alpha^{\text{fe}} = \frac{2\pi}{|\gamma G_\alpha T_2^*|} \quad [9]$$

As an example, with $G = 1 \text{ T m}^{-1}$ and $T_2^* = 1 \text{ ms}$, a maximum resolution for ^1H of $\Delta r_\alpha = 25 \mu\text{m}$ could be achieved. A common cause for short T_2^* is large susceptibility gradients inside an inhomogeneous sample, for

example, at interfaces between different tissues, or due to air-filled pockets in water.

Molecular diffusion imposes a further limit to the maximum resolution of MRM experiments. Since the average distance R_α a molecule travels due to diffusion in one spatial direction during time t is given by

$$\sqrt{\langle R_\alpha^2 \rangle} = \sqrt{2Dt} \quad [10]$$

where D is its self-diffusion constant, it is important to keep the acquisition time short. Minimizing T_{aq} while maintaining the same FOV requires the use of strong gradients. However, there are physical constraints causing an upper limit for G , such as vibrations due to gradient switching, finite dissipation of heat produced in the resistive wires of the gradient coils, or the inductance of the gradient coils that limits the slew rate of the gradient system. Standard pulsed gradient systems can achieve between 20 and 50 $\text{mT m}^{-1} \text{ A}^{-1}$, using amplifiers that can deliver up to 60 A of current. Specially designed gradient systems with a small sample space have been reported in several publications to achieve substantially higher gradients of the order of 10 T m^{-1} and in one case up to 600 T m^{-1} . Images exploring the limit of spatial resolution in MRM have been reported with resolutions of $1 \times 1 \times 75 \mu\text{m}^3$ and an experiment time of 56 min using oil with a low diffusion constant, and with $3 \times 3 \times 3 \mu\text{m}^3$ isotropic resolution and an experiment time of 58 h of glass fibers in water, as shown in **Figure 2**.

Image Contrast

MRM experiments offer unique opportunities to measure, noninvasively and spatially resolved, sample properties such as self-diffusion, molecular translational and rotational motion, as well as local chemical composition in optically opaque material. Furthermore, relaxation time constants such as the longitudinal (or spin-lattice) relaxation time constant T_1 and the transverse (or spin-spin) relaxation time constant T_2 provide information about the molecular environment of the observed nuclear species. Imaging experiments can be made sensitive not only to the spin density $\rho(\mathbf{r})$ but also to the spatial variation of any property that can be measured in an NMR experiment. By cascaded encoding of different sample properties, multidimensional data sets can be obtained where any two of these properties can be correlated with each other.

A particular strength of MRM is quantitative mapping of *motion*. Using pulsed gradient spin echo (PGSE) experiments (**Figure 1(b)**) it is possible to measure the flow vector, the self-diffusion constant, or the acceleration of molecules in a liquid through the application of appropriate combinations of gradient pulses. The basic idea is

Figure 2 High-resolution MRM of glass fibers in H_2O at 18.8 T with isotropic nominal resolution of 3.0 μm . (a) Prototype probe for MRM, with planar rf and gradient coil design. The sample is mounted on a slider plate, together with the rf coil (A). The arrow indicates how this plate is inserted into the gradient socket (D). The gradients are water cooled (B). To ensure long-term stability of an experiment that is recorded over several hours, a ^2H lock is incorporated (C). (b) Magnification of the microfabricated coil and the connecting leads. (c) MRM image recorded parallel to the coil plane. (d) MRM image recorded perpendicular to the coil plane. The white horizontal bars indicate the section displayed in the respective other orientation. From Weiger M, et al. (2008) *Concepts in Magnetic Resonance B* 33: 84–93. Courtesy of M. Weiger.

to create transverse magnetization in the sample with an rf pulse, onto which a spatially dependent phase is added with a gradient pulse. A second gradient pulse applied after an evolution period Δ can only reverse the action of the first gradient pulse if no translational or diffusive motion has affected the periodic phase variation of the sample magnetization. Diffusion during Δ causes a random displacement of molecules, thereby degrading the periodic order and attenuating the amplitude of the echo that is generated after the second gradient pulse.

Coherent translational motion does not change the order of the magnetization, but an additional global phase contribution is added that causes a signal phase shift proportional to the displacement R of the sample during Δ . Knowing R from the measured data and Δ from the gradient timing, the velocity component of the flow parallel to the gradient direction can be calculated. The phase modulation of the signal due to the translational motion and the attenuation due to the diffusive motion can be used to calculate the propagator of a fluid, which fully characterizes the molecular motion occurring in the sample (see the monograph by Callaghan mentioned in the Further reading section). **Figure 3** shows a velocity image of flow in a micromixer.

The timing of an MRM experiment can be used to control the contrast generated by the spatial variation of *relaxation processes* in an MRM image. Long echo times discriminate signal components with short T_2 . When a series of otherwise identical images with varying echo time is recorded, the spatial distribution of T_2 can be retrieved. Correspondingly, short recycle delays between subsequent repetitions of an experiment favor signal components with fast T_1 . An inversion recovery or saturation recovery encoding step allows for a quantitative determination of T_1 . On the other hand, selecting particularly short echo times (relative to T_2) and long repetition times (relative to T_1) minimizes relaxation time weighting of an image, and contrast arising mainly from the spatial variation of $\rho(\mathbf{r})$ is obtained. Quantitative maps of $\rho(\mathbf{r})$ can also be generated by the analysis of a set of relaxation-weighted images and by extrapolating to the image intensity that is not affected by relaxation.

The ‘chemical composition’ of samples can be mapped by MRM experiments using chemical shift imaging protocols, for example, by using a selective encoding rf pulse to only excite signals in a certain frequency range of the NMR spectrum. However, to acquire the data at a reasonably short timescale with microscopic resolution, only small molecules in solution with sufficiently high concentration (>10 mM) can be detected. Cyclic polarization transfer (^1H editing) is another method to obtain chemical selectivity, where maps of molecules labeled with the stable ^{13}C isotope can be recorded. ^{13}C nuclei are detected via their bonded ^1H nuclei with the same sensitivity as with conventional ^1H detection (**Figure 4**). The ^{13}C gyromagnetic ratio $\gamma_{\text{C}-13}$ is only one-fourth of $\gamma_{\text{H}-1}$ and therefore direct ^{13}C imaging is made difficult by the lower SNR of the ^{13}C NMR signal.

Using the polarization of molecules, for example, by prepolarization before the MRM experiment, facilitates the distinction between identical species with a different origin. Prepolarization made it possible to distinguish between fresh water flowing into a vessel and water that was already present before (**Figure 5**), or to observe the

Figure 3 Velocity image of water flow through the channels of a micromixer. The sensitivity was optimized by using a surface rf coil with its diameter adjusted to the sample size. The images were recorded in 58 min with a resolution before zero-filling of $29 \times 43 \mu\text{m}^2$, covering a FOV of $15 \times 22 \text{ mm}^2$. The transverse (a) and longitudinal (b) components of the velocity are shown. The velocity is color-coded, with color bar units of mm s^{-1} . Images from Ahola S, et al. reaction and migration of organic molecules in a catalytic converter (**Figure 6**).

Experimental Strategies for MRM

The primary factors limiting the resolution in MRM are the SNR, relaxation, and diffusion. The SNR or, more importantly for a high spatial resolution, the minimum number of detectable spins determines the minimum voxel volume for a given spin density. Relaxation limits the available time for encoding or detection. Finally, diffusion erodes the localizability of a spin-carrying

molecule and can be aggravated by local field gradients induced by susceptibility variations in a sample. A number of different strategies have been conceived to facilitate MRM for particular types of samples. These can be broadly classified as pulse sequence optimizations, hardware developments, spin polarization enhancement, and sample conditioning.

Hoult and Richards in 1976 showed that the detection sensitivity per spin for a particular coil geometry is proportional to the rf field, $\mathbf{B}_1$, generated by a unit current flowing through the coil. As a general rule, $\mathbf{B}_1$ increases inversely proportional to the coil diameter. Therefore, the SNR per spin can be optimized by using as small a coil as possible for a particular sample, or by reducing the size of a sample to fit into a small coil. Furthermore, the SNR depends on the coil geometry, with solenoids being about three times more sensitive than saddle coils for a given coil volume.

The most basic method to improve the SNR is to perform signal averaging, as the SNR grows with the square root of the number of averages (and therefore with time). Since longitudinal magnetization recovers exponentially with T_1 after an excitation, there is an optimum recycle delay, τ_r , with maximum SNR for a given experiment time. Assuming zero longitudinal magnetization after the last rf pulse of the sequence, this optimal delay is $\tau_r \approx (5/4)T_1$. Doping a liquid with a paramagnetic relaxation agent to reduce T_1 facilitates a quicker repetition of the experiment and an improvement of the SNR obtained in a given amount of time. The best SNR is obtained if $T_1 = T_2$ and $T_2 = T_2^*$, with the SNR scaling roughly proportionally to $(T_2^*)^{1/2}$. Since in many samples $T_2^* \ll T_1$, T_1 can often be considerably reduced without affecting the resolution.

A variety of hyperpolarization strategies have been designed with the potential to increase the nuclear spin

Figure 5 Contrast flow imaging at 0.35 T of water over a packing of submerged sieve beads. The protons in water could be hyperpolarized by DNP using a continuous flow polarization setup located immediately above the imaging probe. (a) Photograph of the sample, showing the inlet and outlet capillaries coming in from the top. (b) Proton magnetic resonance image obtained under continuous water flow at a flow rate of 1.5 ml min^{-1} with the polarizer turned off. The image is stretched along the horizontal direction (the scale bar indicates 1 mm along both axes). (c) Image obtained with the polarizer turned on, producing water with negatively polarized proton spins. The polarized water can be seen entering at the right side of the vessel, then it flows below the bead packing, across the tube, and back up into the outlet capillary. Courtesy of S. Han, as detailed in McCarney E, et al. (2007) *Proceedings of the National Academy of Sciences of the United States of America* 104: 1754–1759.

polarization several orders of magnitude above equilibrium. Dynamic nuclear polarization (DNP) is one such technique where the polarization from electron spins is transferred onto nuclear spins, thereby taking advantage of the three orders of magnitude higher magnetic moment of the electron spins. DNP can be used to prepolarize solvents, where immobilized radicals have been used successfully for flow-mode polarization (Figure 5). Furthermore, small molecules can be prepolarized in the solid state and detected after fast dissolution at very low concentration.

Parahydrogen-induced polarization (PHIP) exploits the spin order of the ^1H nuclei in hydrogen gas at cryogenic temperatures. This spin order can be transferred onto products of catalyzed chemical reactions occurring within the lifetime of the parahydrogen state. In Figure 6 a heterogeneous catalytic reaction of propylene and H_2 gas flowing through a microreactor containing silica gel-supported Wilkinson's catalyst to form propane is monitored. The thermally polarized propylene can barely be resolved, whereas density and velocity maps of the hyperpolarized propane can be recorded with good SNR. The flow map reveals a non-uniform packing of the catalyst, which is not apparent from the density map.

Another hyperpolarization technique is spin-exchange optical pumping, which is also termed laser polarization. This technique, which uses circularly polarized light to selectively populate one spin state of a molecule, is particularly successful for noble gases, such as ^{129}Xe or ^3He , where polarization values close to unity have been reported. Optical pumping can be performed in flow mode, where a continuous stream of hyperpolarized

nuclear spins is generated, or in batch mode, where a certain amount of gas is first polarized, and then this polarization is used up during the MRM experiment.

In soft solid material, the dephasing of transverse magnetization is very fast, since variations of local magnetic fields caused by dipolar interactions with neighboring nuclei are not averaged out by fast molecular motion. Therefore, particularly strong gradients are required for spatial encoding of the FID or echo arising from nuclear spins. One approach is to use the strong constant gradient of the stray field of a magnet (STRAFI). The strength of such gradients can be substantial (up to 60 T m^{-1}), depending on the position relative to the magnet isocenter. Usually the sample is imaged one slice at a time by physically moving the sample or changing the carrier frequency of the excitation rf pulse. An extension of this approach is the development of purpose-designed permanent magnets with curved pole pieces that can generate uniform gradients up to 20 T m^{-1} . The geometry of these magnets is particularly suited to obtain one-dimensional profiles through thin ($\sim 500 \mu\text{m}$ thick) films such as coatings as well as the human skin. This approach was developed even further in the design of a range of portable magnets, such as the single-sided NMR MOUSE (see the review by Blümich et al. mentioned in the Further reading section). Scaling the magnet down in size makes it possible to probe surfaces and layered structures in objects that would otherwise not fit into conventional magnets. Cost-efficient small MRM instruments can now, for instance, be used for quality control in the manufacturing process, for measurements of moisture in building walls, or for analysis of paint layers in antique frescos and oil paintings.

Figure 6 Monitoring a catalytic reaction in a microreactor using PHIP. (a) Density map of thermally polarized propylene. The inset schematically depicts the flow reactor, consisting of the tightly packed catalyst sandwiched between two layers of glass beads for stability. The FOV of $2.3 \times 7.0 \text{ mm}^2$ is indicated by the dashed red line. The pixel size is $20 \times 60 \mu\text{m}^2$, with a catalyst layer thickness of $\sim 5 \text{ mm}$. (b) Density map of parahydrogen-polarized propane. The SNR is a factor 300 larger than that of the propylene image. (c) Flow map of polarized propane. The arrow orientations represent the flow direction and their lengths represent the flow velocity. Images from Bouchard L, et al. (2008) *Science* 319: 442–445. Courtesy of L. Bouchard.

A pulse sequence-based strategy for imaging of soft solid matter is single-point imaging (SPI). In this technique, each point in k -space is sampled using an individual low-angle excitation pulse. The gradient amplitude is incremented after each acquisition. Although this is a very time-consuming procedure, since the required number of excitations equals the size of the data matrix, it enables the acquisition of images of materials with very short T_2 . In the single-point ramped imaging with T_1 enhancement (SPRITE) variant the magnetization is driven into a quasi-equilibrium by repeating the excitation pulses fast in comparison to T_1 of the nuclear spin ensemble. This reduces the experimental time and introduces a contrast due to T_1 variations in the material.

NMR remote detection separates the encoding of spectral and spatial information from the detection of the

actual signal. Information about a stationary object of interest is encoded onto the longitudinal magnetization of a flowing sensor using standard image encoding techniques. The sensor, which could be a hyperpolarized gas such as ^{129}Xe (see Figure 7) or a liquid such as water, is then physically transferred to a different location for detection within a time period on the order of or shorter than T_1 of the sensor nuclear spins. This strategy facilitates the independent optimization of the encoding and the detection and leads to a substantial signal enhancement in comparison to direct detection whenever geometrical constraints prevent the use of a sensitive detection coil directly at the sample site. Remote detection proves to be of particular interest for the study of porous media and, combined with rf microcoils for sensitive detection, for imaging of fluids in microfluidic devices such as microchip reactors, which are increasingly used in small-scale, high-accuracy synthesis.

The experiment presented in (Figure 7) is equivalent to the tracer injection method, but using the spins as internal tracer, with the possibility to tag them at an arbitrary location outside or inside the object of interest. This example illustrates another aspect that makes MRM complementary to optical microscopy: it is possible to completely noninvasively tag a fluid and observe its propagation quantitatively on timescales between the minimum MRM encoding duration, which is typically a few hundred microseconds, and T_1 , which can be up to many seconds.

To overcome the problem of severe signal attenuation due to diffusion in susceptibility-induced field gradients, an rf coil producing a linearly varying rf field across the sample can be employed. The nutation frequency of the local sample magnetization is proportional to the amplitude of the rf field at this position. In analogy to the use of static field gradient pulses, it is therefore possible to encode a spatial dimension by acquiring the NMR signal repetitively while incrementing the duration or amplitude of rf gradient pulses.

Selected Applications

Since MRM offers the unique feature of measuring flow and diffusion in optically opaque material, it is frequently the method of choice in the investigation of porous media. Parameters such as porosity and tortuosity can be determined with spatial resolution. In Figure 8, flow and electric currents in the water-filled pore space of a quasi two-dimensional random site percolation cluster object are visualized.

The characterization of porous rock material using MRM is an important application in the oil industry. Rock cores can be analyzed in the lab, and tools have been developed for field studies using magnetic resonance.

Figure 7 Remotely detected images of gas flow in a microfluidic device, using hyperpolarized ^{129}Xe . The images were encoded using a commercial microimaging probe with a 25 mm sample bore. Detection was done using a microsolenoid coil (400 μm inner diameter, 3 mm long). Both encoding and detection were done in the same magnet at 7 T. (a) Time-of-flight resolved partial images. Each image represents the encoding location of the gas that reached the detection coil at a particular time after the encoding step. Flow was from top to bottom, with gas closer to the outlet of the chip reaching the detector first. A range of MRM applications are related to chemical engineering, in particular to the flow dynamics of solvents in chromatography columns and through membrane systems.

Since MRM is noninvasive and does not use high-energy electromagnetic radiation, it is particularly suited for *in vivo* studies in which the system under consideration is not affected by the measurement. MRM was used

Figure 9 Neuroanatomic MRM image of a mouse brain, measured at 17.7 T. The image was recorded at an isotropic resolution of 47 μm in 11 h with an SNR of 63. Courtesy of S. Blackband.

to measure water flow in the vascular bundle system of plants and small trees, as well as metabolite distributions using either ^{13}C labeling and detecting the signal of ^1H nuclei bound to the ^{13}C nuclei (Figure 4), or chemical shift selective imaging of small molecules such as sugars or amino acids.

MRM has proved to be a valuable tool in the study of changing anatomy in embryogenesis. Furthermore, brain anatomy has been mapped with very high resolution in mice and compiled into a reference atlas (Figure 9), and

in vivo studies of brain activation of small animals have been carried out using MRM.

MRM has found many applications and is still a field of active research, with new experimental strategies being developed, based on continuous hardware improvements as well as novel conceptual ideas. One such example is magnetic resonance force detection, which has the potential to improve the detection sensitivity and based on this the surface or near-surface imaging resolution by several orders of magnitude.

Introduction

Metabonomics is the latest and least mature of the systems biology stable, which also includes genomics, transcriptomics and proteomics, and has its origins in the early orthomolecular medicine work pioneered by Linus Pauling and Arthur Robinson. It was defined by Nicholson and colleagues in 1999 as the quantitative measurement of perturbations in the metabolite complement of an integrated biological system in response to internal or external stimuli, and is often used today to describe many nonglobal types of metabolite analyses. Applications of metabonomics are extensive and include toxicology, nutrition, pharmaceutical research and development, physiological monitoring, and disease diagnosis. For example, blood samples from millions of neonates are tested routinely by mass spectrometry (MS) as a diagnostic tool for inborn errors of metabolism. The metabolome encompasses a wide range of structurally diverse metabolites; therefore, no single analytical platform will be sufficient. Specialized sample preparation and detection techniques are required, and advances in NMR (nuclear magnetic resonance) and MS technologies have led to enhanced metabolome coverage, which in turn demands improved data analysis approaches. The role of MS in metabonomics is still evolving as instrumentation and software becomes more sophisticated and as researchers realize the strengths and limitations of current technology. MS offers a wide dynamic range, high sensitivity, and reproducible, quantitative analysis. These attributes are essential for addressing the challenges of metabonomics, as the range of metabolite concentrations easily exceeds nine orders of magnitude in biofluids, and the diversity of molecular species ranges from simple amino and organic acids to lipids and complex carbohydrates. Additional challenges arise in generating a comprehensive metabolite profile, downstream data processing and analysis, and structural characterization of important metabolites. A typical workflow of MS-based metabonomics is shown in

Figure 1 A typical workflow of MS-based metabonomics. Sample preparation is followed by MS analysis, typically coupled to LC, GC, or CE separation techniques. Data is processed and analyzed, and metabolites of interest are then structurally characterized.

Figure 1. Gas chromatography (GC)-MS was the most commonly used MS-based method for small molecule analysis in the 1970s and 1980s. It is still used today for the detection of many metabolic disorders and plays a strong role in plant metabonomics. Liquid chromatography (LC)-MS, approaches have grown in popularity for metabolite studies, due to simpler sample preparation, reduced analysis times through the introduction of ultrahigh performance liquid chromatography (UPLC)-MS and the ability to observe a wider range of metabolites. This article will discuss the role of MS in metabonomics, the techniques involved in this exciting area, and the current and future applications of the field. The various bioinformatics tools and multivariate analysis techniques used to maximize information recovery and to aid in the interpretation of the very large datasets typically obtained in metabonomics studies will also be discussed. Although there are many different MS-based approaches utilized in metabonomics studies, emphasis will be placed on more established methods.

Sample Preparation

The complex biological matrices used in metabonomics studies require preparation before analysis, with the choice of method having a large impact on the quality of

results obtained, both in the number of detected metabolites and in the reproducibility of their detection. Sample preparation serves several purposes: to extract metabolites from the relevant matrix, to remove interferences due to matrix components (e.g., proteins, salts, and endogenous peptides), and, in some instances, to preconcentrate low-level analytes. Sample preparation will inevitably cause analyte losses and possibly introduce artifacts; therefore, a minimal approach is preferred. Method optimization is crucial, and the chosen protocol should be as simple, reproducible, effective, and universal as possible. Common extraction methods include solid phase extraction (SPE) and liquid-liquid extraction (LLE) with concomitant protein precipitation. The variety of biological matrices being studied dictates that not all require the same degree of preparation. For example, relatively simple biofluids such as urine require dilution and centrifugation or filtration before injection onto an LC column, or perhaps a simple clean up step such as SPE using a C18 cartridge. Conversely, more complex samples such as serum, plasma, or cerebrospinal fluid, which contain high levels of proteins, require a deproteinization step, usually with a cold organic solvent such as methanol or acetonitrile. Failure to carry out this step would result in poor analytical reproducibility, reduced column life, and immense ionization suppression due to the presence of proteins. Tissues such as liver require

extensive sample preparation such as homogenization followed by Bligh-Dyer extraction, which results in two phases to be analyzed separately – one containing more polar molecules and the other predominantly lipids. The partitioning of water- and lipid-soluble metabolites has also been advocated for serum and plasma samples, as lipids can interfere with the detection of other metabolites when LC-MS is employed with electrospray ionization (ESI). For samples to be analyzed by GC-MS, chemical derivatization of nonvolatile functional groups is required after metabolite extraction. Similarly, matrix-assisted laser desorption ionization (MALDI) analysis requires extracted metabolites to be cocrystallized with a matrix. Typically, for use with ultraviolet lasers, this matrix is an aromatic acid with a chromophore to absorb the laser wavelength. Other key properties of a MALDI matrix are its solubility in solvents compatible with the analyte of interest and the ability to cause codesorption of the analyte on laser irradiation and to promote analyte ionization. In contrast, desorption ionization on silicon (DIOS) requires no such matrix, and the samples are deposited directly onto the plate for analysis.

Separation Techniques

Although suitable preparation may simplify samples through the removal of macromolecules, it is still desirable to separate metabolites before MS detection. This reduces the dynamic range of metabolite concentrations delivered to the MS at any one time. In addition, it minimizes ionization suppression when ESI is utilized. The most common separation approaches in metabonomics are GC, LC, and capillary electrophoresis (CE).

Gas Chromatography

GC-MS is a very popular tool for metabolite profiling, with the majority of applications focused on plant metabonomics and screening for inborn errors of metabolism. Advantages of GC over other techniques include high separation efficiency, ability to distinguish isomeric compounds, reproducibility, accessibility of instrumentation, ease of use, robustness, and low cost. The standardization of the electron ionization (EI) source to 70 eV by the GC-MS industry usually results in extensive and highly reproducible fragmentation, enabling metabolites to be identified by matching their mass spectral fragmentation patterns to data from other laboratories, or contained in databases such as the National Institute of Standards and Technology (NIST) and Wiley databases. However, this extensive fragmentation often means that the molecular ion is not detected, which may hinder the identification of unknown compounds. Specialized software platforms such as AMDIS, AnalyzerPro, and LECO Chroma-TOF can be used to analyze the

large GC-MS metabonomics datasets produced. Disadvantages of GC include time-consuming derivatization of nonvolatile molecules, lengthy analysis times (compared to UPLC-MS), and limitations on the size and type of molecule that can be analyzed (large, polar molecules are not suitable). Drawbacks of derivatization include the fact that different metabolites have varying affinities for reagents, increasing the risk of inaccurate quantification due to incomplete derivatization (this can be ameliorated through the use of derivatized standard compounds and data correction strategies to normalize for such a bias). Additional drawbacks include (1) formation of by-products, (2) possible conversion of analytes (e.g., arginine is converted into ornithine by reaction with BSTFA or MSTFA), and (3) degradation of the final product(s). These issues could lead to data misinterpretation, including mis- or nonidentification of metabolites. However, despite these drawbacks, GC-MS can offer complementary information to that obtained using LC and CE.

There have been significant advances in GC-MS in recent years. For example, multidimensional separation techniques such as GC $\times$ GC coupled with time-of-flight (TOF) MS have been developed to address the extremely complex nature of the biological samples analyzed in metabonomics studies. GC $\times$ GC experiments offer dramatically improved peak separation, increased sensitivity, and improved mass measurement accuracy when coupled with TOF-MS. In addition, higher coverage of the detectable metabolome can be achieved *via* improved selectivity through the utilization of two different GC columns (i.e., polar/nonpolar). However, due in part to its high cost, GC $\times$ GC-TOF-MS is not yet routinely used in metabonomics studies.

Liquid Chromatography

LC-MS is now a more commonly employed metabonomics tool than GC-MS, with applications in toxicology, cancer, and nutrition research. LC-MS provides a selective approach that allows for both quantitative and structural information, and can achieve picogram-per-milliliter sensitivities. Advantages of LC-MS over GC-MS include simpler sample preparation (there is generally no need for derivatization) and, with the advent of UPLC-MS, shorter analytical run times. In addition, there is less restriction on the type and size of molecule being analyzed.

An important factor in metabolite separations by LC is the choice of stationary phase. Metabonomic samples are extremely complex and contain a large number of molecules differing greatly in polarity. For example, urine contains a vast array of highly polar molecules that are not retained well on reversed-phase (RP) LC columns. This leads to perhaps hundreds of molecules eluting in the void volume of the analytical run, resulting

HPLC

UPLC

Figure 2 Three-dimensional plots representing (a) HPLC-MS and (b) UPLC-MS data from the same white male mouse urine sample. Retention time, m/z , and intensity are shown. Reproduced from Wilson ID, Nicholson JK, Castro-Perez J, et al. (2005) High resolution “ultra performance” liquid chromatography coupled to oa-TOF mass spectrometry as a tool for differential metabolic pathway profiling in functional genomic studies. *Journal of Proteome Research* 4(2): 591–598, with permission of the American Chemical Society.

in poor sensitivity and reproducibility due to ionization suppression. A newer approach for the analysis of highly polar molecules is hydrophilic interaction chromatography (HILIC), which offers complementary separation characteristics to that obtained using RP chromatography. Here, ‘traditional’ RP mobile phases such as water and acetonitrile are used, with the gradient starting from a high organic content and ending at high aqueous. HILIC approaches have already been applied to the analysis of metabolites in blood, tissues, and plants.

The ability of conventional LC to separate efficiently complex mixtures before mass analysis comes at the cost of speed, with serum analyses requiring up to 1 h per sample. This is obviously not ideal for large-scale studies. Many stationary-phase manufacturers now offer sub-2 μm particles, such as those used in UPLC. This technique utilizes columns with 1.4–1.7 μm particles, thus allowing for improved metabolite separation and higher resolution than traditional columns. Pumping and injection of liquids is performed at pressures exceeding 10 000 psi; therefore, LC systems with valves and fittings capable of tolerating these extreme pressures are required. Using this approach, sample analysis times can be reduced to as little as 1 min, resulting in greater sample throughput, though typical metabonomics studies would employ run times of 10–30 min depending on the sample type. With UPLC, narrower chromatographic peaks can be achieved (peak widths at half-height can be <1 s), resulting in increased peak capacity, lower ionization suppression, and improved signal-to-noise ratio – all of which result in increased sensitivity. UPLC and HPLC

have been compared directly for their application to metabonomics studies, and it was shown that more components were detected using UPLC than HPLC, with a 20% increase reported over the same chromatographic length and superior retention time reproducibility and signal-to-noise ratios. A potential disadvantage of UPLC is the relatively high flow rates employed ($0.2\text{--}0.8\text{ mL min}^{-1}$), which may minimize the utility of this approach in sample-limited situations, where solvent-related ions and ion clusters can contribute to MS background or otherwise suppress low-abundance metabolite ions. **Figure 2** illustrates the increase in the number of detected peaks from the same urine sample when using UPLC as opposed to HPLC.

Capillary Electrophoresis

Although used less frequently in metabonomics studies than GC or LC, CE can offer advantages for the analysis of complex metabolite mixtures, namely high separation efficiencies, easily optimized resolution, applicability to a wide range of sample types (including intact micro-organisms), small sample injection volumes (nl range), and low reagent costs. In CE, metabolites are separated based on charge and size. Commonly utilized with ESI, CE-MS can also be used for structural elucidation via tandem mass spectrometry (MS/MS). However, a major drawback of CE is the lack of sensitivity due to small sample injection volumes, especially when coupled to MS. Metabolite databases for CE are also limited, relative to GC and LC.

Ionization Methods

Electron and Chemical Ionization

Once the components of a biological sample have been separated sufficiently, they must be transferred into the vacuum environment of the spectrometer in the form of ions suitable for mass analysis. In GC, samples are vaporized and then ionized using electron (EI) or chemical ionization (CI). In EI, analytes in the gas phase are bombarded by high-energy electrons, which provides good sensitivity and unique fragmentation. Extensive libraries of EI spectra are available to aid in the identification of molecules, such as the NIST and Wiley databases. A disadvantage with EI is the limited mass range due to the requirement of thermal desorption. In contrast, CI relies on chemical reactions between reagent gas ions and analyte molecules. It is much less energetic than EI, producing more stable ions in general, which is

useful for identifying the molecular ion and thus determining the molecular weight of a compound. Negative CI is particularly sensitive for perfluorinated derivatives and provides a limited but powerful approach for certain derivatized molecules such as steroids. However, CI still requires thermal desorption, and quantification is difficult without internal standards.

Atmospheric Pressure Ionization

Commonly, LC is coupled with an atmospheric pressure ionization (API) source to convert analytes in the LC eluent into gas-phase ions. API techniques include ESI (illustrated in **Figure 3**) and atmospheric pressure chemical ionization (APCI). For metabonomics studies, ESI is most commonly used in conjunction with LC-MS. With this technique, the solution (in this case eluent from the LC) is nebulized to create a fine spray of charged

Figure 3 Illustration of microelectrospray and nanoelectrospray. Various factors lead to improved ESI efficiency during nano-ESI as compared with conventional-ESI. Ions depicted represent analyte ions only. Typically, each droplet would also contain many counterions from the LC solvent. Reproduced from Metz TO, Zhang Q, Page JS et al. (2007) Future of liquid chromatography-mass spectrometry in metabolic profiling and metabolomic studies for biomarker discovery. *Biomarkers in Medicine* 1(1): 159–185, with permission of Future Medicine Ltd.

droplets. Solvent evaporation occurs as the droplets traverse the atmospheric interface, thus introducing molecular ions into the analyzer. ESI offers soft ionization, excellent quantitative analysis, and high sensitivity. In addition, it is well suited to automated sample analysis. ESI can be quite effective even without separation, especially when combined with MS/MS, where its direct application to metabolite screening is currently used for over 35 diseases. A disadvantage of ESI is the need for either acidic or basic functional groups on the molecules of interest capable of losing or gaining a proton during negative or positive ESI, respectively. Neutral molecules can be detected as salt adducts but their ionization efficiency is lower than those molecules containing ionizable functional groups. Although APCI is not as widely used as ESI in MS-based metabonomics, it can be a valuable technique for the analysis of both nonpolar and thermally stable neutral molecules, such as lipids. APCI analysis of more easily ionizable molecules, such as phospholipids, can produce molecular and fragment ions complementary to those produced by ESI-MS with collision-induced dissociation (CID). In addition, APCI provides a higher dynamic range than ESI and is considered robust, easy to operate, and relatively more tolerant of higher buffer concentrations, due to a less collimated spray.

Desorption Ionization

In desorption ionization (DI) methods, molecules are commonly embedded in a matrix and introduced into the vacuum system, where they are rapidly desorbed and ionized using energetic charged particles or laser beams. Perhaps the best known of these approaches is MALDI, a soft ionization technique used in conjunction with MS primarily for the analysis of proteins, peptides, polymers, and sugars. MALDI has similarities with ESI, both in the softness of ionization and the ions produced (although fewer multiply charged ions are formed using MALDI). The sample is cocrystallized with a matrix to protect the molecules from being destroyed by the direct laser beam (normally a nitrogen laser) and to facilitate vaporization and ionization. DIOS is similar to MALDI, but the absence of matrix allows for the analysis of small molecules as well as proteins, thus lending it to applications in metabonomics. DIOS surfaces are produced through a simple galvanostatic etching procedure, and despite the absence of matrix, DIOS-MS yields little or no fragmentation and is relatively tolerant of moderate amounts of contaminants commonly found in biological samples.

The composition of solid surfaces and thin films can be analyzed using secondary ion mass spectrometry (SIMS). With this technique, the surface of the specimen is sputtered with a focused primary ion beam and charged ejected secondary ions are collected and analyzed by MS. The elemental, isotopic, or molecular

composition of the surface can be determined in this way. SIMS is the most sensitive surface analysis technique, as elements can be detected when present in the parts per billion range.

Complementary Approaches

It is important to note that some compounds do not ionize well using any of the common ionization techniques described above and so will not be detected using MS alone. Thus, complementary approaches may be required to enable complete detection, quantitation, and identification of the metabome. The coupling of NMR and MS has been used in combination with liquid chromatography (LC-NMR-MS) and applied to metabonomics, such as in the pharmaceutical drug discovery area. This technique allows for both MS and NMR data to be collected from a single LC run – the complementary information obtained makes this approach a powerful tool for the detection and identification of both known and unknown compounds. Further, software is being developed to analyze the complex data produced from LC-NMR-MS experiments; in particular, statistical heterospectroscopy (SHY), an approach to the integrated analysis of NMR and UPLC-MS datasets, could prove a valuable tool.

Mass Analyzers

Mass spectrometers have become more sophisticated in recent years, offering sensitivity, mass accuracy, and a wide dynamic range for the measurement of metabolites. In the context of metabonomics studies, mass spectrometers can be divided into two categories: low-mass resolution and high-mass resolution.

Low-Mass Resolution Instruments

Low-mass resolution mass spectrometers include single and triple quadrupoles and quadrupole ion traps, which are capable of measuring the masses of metabolites with unit resolution. Quadrupole instruments are the most common mass analyzers in existence today and are essentially mass filters. They can be coupled to many different ionization sources and are mainly used for simple screening applications. Advantages of quadrupoles include robustness, tolerance of high pressure, capability of scanning a wide mass range (up to m/z 4000), and low cost. Tandem mass analysis can be performed using a triple quadrupole instrument, where each quadrupole has a separate function. The first quadrupole (Q1) scans across a preset m/z range for selection of an ion of interest, which is then fragmented in the second quadrupole (Q2; also known as the collision cell) using a

collision gas (argon or helium). In modern triple quadrupole instruments, Q2 is typically an octapole. The fragment ions generated in Q2 can either be analyzed in the third quadrupole (Q3) or subjected to further selection, resulting in a so-called selected reaction monitoring (SRM) experiment. The SRM capability of triple quadrupole instruments is a highly specific and therefore highly sensitive approach for quantifying known metabolites during targeted metabolic profiling experiments. The quadrupole ion-trap mass analyzer can be used for both MS scanning and MS/MS studies. It differs from the linear quadrupole in that mass analysis is a discontinuous, pulsed process, whereas linear quadrupoles provide continuous transmission of ions. A key characteristic of the quadrupole ion trap is the ability to isolate a single ion species by ejecting all others from the trap, whereby the isolated ions can subsequently be fragmented through collisional activation and the fragments detected. Another notable feature of the quadrupole ion trap is the ability to perform MSⁿ experiments, where multiple CID experiments can be performed serially. A particular disadvantage to quadrupole ion traps is the upper limit on the ratio between precursor m/z and the lowest trapped fragment ion, which is ~ 0.3 (the 'one-third rule') and is a disadvantage for small molecule analysis. In general, low-mass resolution mass analyzers are not desirable for global, untargeted metabonomic studies, as they lack sufficient resolution to resolve co-eluting metabolites having the same nominal mass.

High-Mass Resolution Instruments

High-mass resolution mass spectrometers offer resolutions from 5000–10 000 for TOF and quadrupole-TOF (Q-TOF) to 100 000 and 500 000 for Orbitrap and Fourier transform ion cyclotron resonance (FTICR also known as FTMS), respectively. High-mass resolution is a distinct advantage when measuring complex metabolomic samples, both in terms of detection of distinct species and in structural elucidation of unknown compounds. TOFs and Q-TOFs have virtually unlimited mass ranges and offer fast scanning capabilities and accuracies on the order of 5 parts per million (ppm). Owing to their fast scanning speeds, TOFs and Q-TOFs are widely used in GC-, UPLC-, and MALDI-based metabonomics studies. Further, Q-TOF mass analyzers are highly suited for obtaining metabolite fragmentation data. The quadrupole is used to selectively isolate a precursor ion and direct it into the collision cell, where the resultant fragment ions are analyzed by the TOF mass analyzer, achieving simultaneous and accurate measurements of ions across the full mass range. Alternatively, FTMS offers the highest mass resolution and mass measurement accuracy (subparts per million) of all analyzers, as well as very high sensitivity (attomol).

Furthermore, FTMS allows more advanced structural and thermodynamic elucidation of molecules to be undertaken, with the ability to perform high-mass measurement accuracy MSⁿ experiments, often at ppm level. Ultrahigh resolution FTMS can be coupled to MALDI, ESI, APCI, and EI, whereas the more recently introduced hybrid quadrupole-FTMS and quadrupole linear ion trap FTMS (e.g., LTQ-FT) mass analyzers are typically coupled to ESI sources. Due to the externally calibrated accurate mass determination for both parent and product ions, the LTQ-FT is a powerful analytical tool for metabonomics studies, allowing for both the confirmation of known and the structural elucidation of unknown metabolites. Finally, a newer innovation in mass analyzers is the Orbitrap mass spectrometer developed by Alexander Makarov and colleagues, which is an electrostatic ion trap using fast Fourier transformation (FFT). The Orbitrap provides high-mass accuracy (1–2 ppm) and resolution, as well as a dynamic range of 5000. In general, the Orbitrap is usually operated as a hybrid instrument together with a linear ion trap.

Data Processing

MS-based metabonomics studies generate large, complex datasets that require sophisticated software to enable interpretation. Each analysis can produce a data file >100MB in size; therefore, a major challenge is converting these datasets into organized data matrices for further statistical processing, such as multivariate analysis, as well as visualization. An example workflow for data processing using the XCMS software is shown in **Figure 4**.

A typical metabonomics study could involve the comparison of two or more sample groups such as healthy versus disease or dosed versus control. Metabolite features (characterized by monoisotopic mass or m/z and elution time) must first be defined, aligned across all datasets (here a dataset refers to the data obtained from a single LC-MS analysis), and then their relative abundances compared to elucidate any differences between the groups. It is imperative that the same metabolite features are identified correctly in all samples to enable this comparison. The formation of multiple adducts and dimers using ESI increases the number of features detected, complicating data interpretation. Several software options for feature detection, alignment, and evaluation are available from most mass spectrometer manufacturers, as listed in **Table 1**.

However, some researchers desire the freedom to modify many of the filtration, feature detection, and alignment parameters involved in metabonomics data processing, as well as to compare data from different instruments. This has led to the development of many freeware packages including MZmine, XCMS, and

Figure 4 Data processing workflow for MS-based metabonomics using XCMS as the data preprocessing software. Metabolites are detected, aligned, and reported in matrix format where samples (observations) constitute the columns and the features (variables) constitute the rows. Features are normalized and sorted according to the p -value obtained through a t -test. Features displaying significant differences ($p < .05$) between sample groups A and B are reintegrated, normalized, and sorted again according to p -value. Compounds with $p < .05$ constitute the final table of metabolites differing between A and B. Reproduced from Nordström A, O'Maille G, Qin C, Siuzdak G (2006) Nonlinear data alignment for UPLC-MS and HPLC-MS based metabonomics: Quantitative analysis of endogenous and exogenous metabolites in human serum. *Analytical Chemistry* 78(10): 3289–3295, with permission of the American Chemical Society.

Table 1 Commercial software for processing of MS metabonomics data

Software	Manufacturer	Capabilities
Bluefuse	BlueGnome	MS and NMR data: filtering, feature detection, alignment, multi-variate data analysis
Markerlynx	Waters	LC-MS data: feature detection, alignment, PCA
MarkerView	Applied Biosystems	LC-MS data: feature detection, alignment, PCA
MassHunter	Agilent Technologies	LC-MS data: detection/extraction, alignment
Metabolic Profiler	Bruker Daltonic	MS and NMR data: data bucketing (retention time, m/z values), PCA
metAlign	PlanResearch International	LC-MS, GC-MS data: filtering, baseline correction, feature detection, alignment
Profile	Phenomenome Discoveries	MS data: feature detection, alignment, statistical analysis

MET-IDEA, as detailed in **Table 2**. These tools are generally freely available for download and, in some cases, user modifications are permissible.

A significant challenge associated with metabonomic data analysis is data classification, either with or without

a priori knowledge of which classes exist. The application of multivariate statistical analysis for biomarker discovery has facilitated the discovery of hidden structure, particularly in large datasets. Therefore, with many of these software programs, both manufacturer derived and

Table 2 Freeware for processing of MS metabonomics data

<i>Software</i>	<i>Data type</i>	<i>Capabilities</i>
Chrompare	GC-FID	Feature list and raw chromatogram comparison, normalization
COMSPARI	LC-MS and GC-MS	Visualization capabilities for investigating differences between two runs
MathDAMP	LC-MS, GC-MS, CE-MS	Direct data comparison (no feature detection), binning, baseline subtraction, smoothing, normalization
MET-IDEA	LC-MS, GC-MS, CE-MS	Ion intensity data extraction – outputs list of <i>m/z</i> retention time values
MSFACTs	LC-MS, GC-MS	Alignment and comparison of feature lists or raw chromatograms
MZMine	LC-MS, GC-MS	Filtering, feature detection, alignment, normalization, visualization
XCMS	LC-MS, GC-MS	Filtering, feature detection, alignment, visualization

freeware, data (as feature lists or similar) can be output in a suitable format to be analyzed using multivariate statistics. Often this output will be in the form of '*m/z*–retention time' pairs with the corresponding intensity (height or area) for each detected feature. Multivariate techniques can help to discern features with high discriminating power between the sample groups being analyzed. Many companies and research groups involved in metabonomics research augment these available data mining techniques with in-house software, thus enabling further compound identification and quantification.

Data Analysis

Multivariate statistics employed for metabonomics studies can be divided into unsupervised and supervised methods. Unsupervised methods include principal components analysis (PCA) and hierarchical cluster analysis (HCA), where the algorithm is not given a training set and so input data is classified in an 'unsupervised' manner. PCA can be used in the reduction of data dimensionality, to investigate clustering tendencies, to detect outliers, and to visualize data structure. However, PCA gives a simplified representation of the information contained in the data matrix and generally cannot make use of additional metadata. HCA organizes information about variables in a data matrix, forming 'clusters,' where the degree of association is strong between samples within the same cluster and weak between those in different clusters. HCA may reveal previously hidden associations and structures in data and can be represented as a tree, or dendrogram, where each step in the clustering process is illustrated by a branch of the tree. Supervised methods include discriminant analysis (DA), such as projection to latent structures (or partial least-squares (PLS)) and orthogonal projection to latent structures (O-PLS). In contrast to unsupervised methods, a classification system is given a 'training set' (input data together with the classification), which can be used to build a model and estimate necessary parameters. Unsupervised methods such as PCA are often followed by PLS-DA or O-PLS-DA, where PLS-DA is performed to enhance the separation between groups of observations,

often by rotating PCA components to achieve maximum separation between classes, and to understand which variables are responsible for separating the classes. O-PLS-DA is similar to PLS-DA, but has improved predictive capability because the structured noise is modeled separately; it has been used in conjunction with STOCYSY (statistical total correlation spectroscopy) in the analysis of NMR metabonomics data.

Databases

As the collection of MS-based data and subsequent comparative analysis becomes more refined and robust, a major challenge lies in structurally characterizing the metabolites that potentially discriminate between sample groups. In contrast to the well-annotated gene and protein databases that are amenable to automated data analysis complete with identification confidence metrics, metabolite databases are still relatively immature. However, current metabolite databases, although incomplete, offer a starting point for metabolite characterization. Among these, the most widely used are the NIST database (<http://www.nist.gov/srd/nist1.htm>), Kyoto Encyclopedia of Genes and Genomes (KEGG; <http://www.genome.jp/kegg/ligand.html>), HumanCyc (<http://biocyc.org>), the Human Metabolome Database (HMDB; <http://www.hmdb.ca/>), and METLIN (<http://metlin.scripps.edu/>) database (Table 3). The HMDB and METLIN databases act as electronic repositories for identification of small molecule metabolites, containing information for thousands of endogenous and drug metabolites. These databases include MS spectra and in some cases MS/MS spectra for many metabolites to enable comparison with experimental data; the HMDB also contains experimental and predicted ¹H and ¹³C NMR data for some metabolites. HumanCyc includes known metabolites as well as those predicted by algorithms that project metabolic pathways from a genomic sequence. The Spectral Database for Organic Compounds, SDBS, provides access to a wealth of spectra (NMR, MS, and IR) for organic compounds. LIPID MAPS (<http://www.lipidmaps.org/tools/index.html>) is invaluable for the investigation of lipid metabolites. The KNApSACK database (<http://kanaya.aist-nara.ac.jp/>) is

specific for secondary metabolites and allows for MS-based data searches. Some databases focus purely on EI data. For example, the NIST database contains over 220 000 spectra of nearly 200 000 unique compounds in its EI MS library, often with chemical structures, plus over 224 000 Kovats retention index values for almost 22 000 compounds, obtained using both polar and non-polar columns. Similarly, the Wiley database contains nearly 400 000 EI mass spectra and over 180 000 chemical structures. These two databases can now be purchased together, offering a huge resource for metabolite identification through GC-MS. The GOLM open access database at the Max Planck Institute of Molecular Plant Physiology also focuses on EI data and functions as a repository for experiments performed at this institute, as well as for data collected by collaborators.

Metabolite Identification

Once potential biomarkers have been selected from metabonomics studies, precise identification is required. This remains the greatest challenge facing MS-based metabonomics. Fortunately, some metabolites are already well-characterized and can be identified in experimental data through database searches. If samples are analyzed using high-resolution MS, then many candidates can be excluded at this stage. Once candidate molecules are obtained, cochromatography and comparison of MS/MS data are necessary to confirm the identification of the molecule. If the molecule is not known then the next task is *de novo* identification – a significant challenge given the often limited sample amount and trace quantities of some metabolites. The overall procedure can be summarized in **Figure 5**. Methods for obtaining elemental composition are based on accurate mass determinations using high-resolution FTMS or Orbitrap technology, together with tandem mass measurements (often on a Q-TOF, LTQ-FT, or LTQ-Orbitrap) for structural characterization using CID. Orthogonal acceleration TOF and Q-TOF-MS are also used to obtain high accurate mass measurements.

However, despite the usefulness of MS and MS/MS data, the lack of comprehensive mass spectral libraries often precludes identification of molecules based on this information alone. Ultimately, the combination of many technologies and approaches will be required to identify unknown metabolites in biological samples, including high-sensitivity capillary NMR (structural characterization down to low microgram levels), chemical modification for functional group identification, and finally independent synthesis for verification.

Applications

As touched on in the Introduction section, metabonomics applications are quite extensive and can range from toxicology to metabolic engineering to nutrition. One obvious application of metabonomics is in functional genomics studies, such as the elucidation of natural substrates for poorly characterized enzymes. Saghatelian and colleagues applied LC-MS-based metabonomics in the study of the nervous system metabolome of wild-type mice and mice lacking the enzyme fatty acid amide hydrolase. They identified several endogenous substrates for this enzyme, including known signaling lipids and a novel class of central nervous system metabolites (taurine-conjugated fatty acids). This study represents the true essence of global, untargeted, MS-based metabonomics: samples from wild-type and knockout mice were first profiled, followed by comparative data analysis to identify significantly altered features, and the chemical structures of the significant features were finally elucidated based on targeted MS/MS and accurate mass data. Other important applications of metabonomics include the discovery of novel biomarkers of disease and toxicity assessment of new pharmaceuticals. Metabonomics applications that are expected to grow in the near future include metabolic engineering as it relates to bioenergy, as well as human health and nutrition and the interplay between human metabolism and the metabolism of the

Figure 5 Metabolite identification workflow using MS. Compound(s) of interest can be first isolated using chromatography. Characterization is facilitated through (1) accurate mass measurements that provide an elemental composition and (2) tandem mass spectral data that provide structural information. Ultimately, synthetic standards are generated to confirm identification, perhaps in combination with other spectroscopic data. Reproduced from Want EJ, Nordström A, Morita H, Siuzdak G (2007) From exogenous to endogenous: The inevitable imprint of mass spectrometry in metabolomics *Journal of Proteome Research* 6(2): 459–468, with permission of the American Chemical Society.

gut microflora. In particular, growing bioenergy initiatives should provide a driver for metabonomic monitoring of the engineering of various bacteria to produce ethanol from lignocellulose. It has been speculated that a single strain of bacteria will be unable to perform this task and that multiple strains containing the necessary cellular machinery will be required to work in symbiosis to perform the necessary steps to produce the final product. Once identified, these strains will be engineered to increase the efficiency of their respective tasks during this process.

Introduction

Tandem mass spectrometry (MS-MS) currently is an important technique, both in fundamental studies concerning the behaviour and structure of gas-phase ions, and in many analytical applications of MS. The history of MS-MS can be considered to go back to the observation and explanation of metastable ions by Hipple and Condon in 1945. Subsequently, the potential of metastable decompositions of ions was further investigated on magnetic sector instruments. MS-MS as a technique gained momentum in the mid-1970s. Reversed-geometry double focusing sector instruments were built in the laboratories of Cooks and of McLafferty and used for MS-MS studies, and the commercial ZAB range of sector mass spectrometers became widespread. The next major breakthrough was the introduction of triple-quadrupole instruments by the group of Yost in the early 1980s. Commercially available triple-quadrupole systems with an easy user interface stimulated the analytical use of MS-MS, which previously was primarily used in more fundamental studies. More recently, MS-MS applications have been implemented with other types of mass analysers, i.e. ion trap, time-of-flight (TOF) and Fourier-transform ion-cyclotron resonance (FT-ICR) mass spectrometers.

The principles, instrumentation and some (analytical) applications of MS-MS are reviewed in this article. More elaborate accounts on MS-MS may be found in the Further Reading section.

Principles of MS-MS

A basic instrument for MS-MS consists of a combination of two mass analysers with a reaction region between them. While a variety of instrument setups can be used in MS-MS, there is a single basic concept involved: the measurement of the m/z of ions before and after a reaction in the mass spectrometer; the reaction involves a change in mass and can be represented as

where m_p^+ is the precursor (or parent) ion, m_d^+ is the product (or daughter) ion, and m_n represents one (or more) neutral species. In terms of mass: $m_p = m_d + m_n$.

The basic MS-MS experiment is the mass selection of the precursor ion in the first stage of analysis, the fragmentation of the precursor ion, e.g. metastable or by collision-induced dissociation (CID), and the mass analysis of the product ions in the second stage of analysis (product-ion scan).

The fragmentation of the precursor ion depends on the activation barrier of the reaction. The energy to overcome this barrier is due to the excess energy deposited in the precursor ion during ionization and transfer to the first mass analyser and, when applied, to the internal energy of the precursor ion gained by ion activation.

A metastable ion is an ion which during the ionization gained sufficient internal energy for fragmentation, but survived long enough to be extracted from the ion source. Such an ion may dissociate spontaneously during its flight from the ion source to the detector. Double-focusing sector instruments can be used to detect the metastable ions.

However, in most cases, ion activation in a reaction region is applied to increase the internal energy of the ions transmitted from the ion source. Although ion activation by photodissociation and surface-induced collisions has been described, the most widely applied method is collisional ion activation. The CID process results from the conversion of translational energy of the precursor ion into internal energy by collisions with a neutral target gas, e.g. helium or argon, admitted to the collision cell.

In CID, two collision-energy regimes should be considered: low-energy and high-energy collisions, depending on the initial translational energy of the precursor ion upon collision. High energy collisions (kV energy) are applicable in magnetic sector instruments as well as in certain applications of post-source decay in TOF instruments (see below), while low energy collisions are applied in most other systems (triple-quadrupole, ion trap and FT-ICR).

While in principle any ion generated in the ion source by any ionization technique can be subjected to MS-MS in the product-ion mode, MS-MS has especially found analytical applications in combination with soft ionization techniques, where without MS-MS only information on the intact molecule is obtained and no fragmentation is observed. MS-MS is then required to achieve structure informative fragmentation. However,

there are some limitations as well. First of all, the fragmentation in CID may not always lead to sufficient fragmentation to allow unambiguous structure assignment. Furthermore, MS-MS is limited in practice to ions up to m/z of ~ 2000 because with larger ions the number of degrees of freedom is so large that the internal energy gained in CID is readily dissipated over a large number of bonds and no single bond acquires sufficient energy for cleavage on the observational time-scale of the instrument.

In addition to the product-ion scan, most MS-MS instruments allow other scan modes, e.g. neutral-loss and precursor-ion scan modes. The modes are useful not only in the elucidation of the fragmentation pattern of a particular compound, but also in the screening for a series of structurally related compounds in complex samples. In the product-ion scan mode, the first mass analyser selects a particular precursor ion, while the product ions obtained by CID of this precursor are analysed in the second mass analyser. In the precursor-ion scan mode, this process is virtually reversed: the first mass analyser transmits all ions in a preset m/z window to the collision cell, while the second analyser selects only the ions of one particular m/z , e.g. a particular structure informative fragment for a series of ions or compounds. An example of the use of the precursor-ion scan mode is the monitoring of phthalate plasticisers by means of the common fragment ion at m/z 149 due to protonated phthalic anhydride. In the neutral-loss scan modes, both mass analysers are operated in the scanning mode, but at a fixed mass (m/z) difference, corresponding to a characteristic neutral loss. An example of the use of the neutral-loss mode is the monitoring of the CO_2 loss from deprotonated carboxylic acids. In addition, selective reaction monitoring (SRM) can be applied to monitor a specific reaction in the mass spectrometer. Both mass analysers are operated in the selection mode, i.e. selecting a particular precursor ion in the first and a particular product ion in the second mass analyser. SRM is extremely useful in the quantitative analysis of compounds in complex matrices, as a significant gain in selectivity may be achieved, leading to improvement of detection limits.

Instrumentation for MS-MS

A wide variety of instruments for MS-MS are available.

MS-MS in Sector Instruments

Initially, the study of metastable ions was performed using sector instruments. In a double-focusing magnetic sector instrument, a variety of MS-MS related experiments may be performed. Two reaction regions may be used in the field-free regions, i.e. between the ion source

and the first sector and in between the two sectors (RR1 and RR2 in **Figure 1a**). A fragmentation reaction in the first field-free region of an instrument with either geometry (EB or BE) can be monitored using linked scan experiments. In a linked scan, both the magnetic field strength B and the electrostatic sector voltage are scanned but maintained in a fixed relationship throughout the scan, e.g. B-E linked scans for product-ion scans and B^2 -E linked scans for precursor-ion scans. A disadvantage of the linked scan procedures is the limitation in resolution (typically ~ 1000 for the precursor ion and ~ 5000 for the product ion). The product ions generated in the second field-free reaction region of a reversed-geometry instrument (BE) may be monitored via a mass-analysed ion kinetic energy (MIKE) scan, where the electrostatic sector voltage is scanned while maintaining a constant magnetic field and accelerating voltage.

More advanced possibilities for MS-MS in sector instruments can be achieved in three- and four-sector instruments. The four-sector instruments enable MS-MS with high-resolution selection/analysis for both precursor and product ions. CID is performed with high-energy collisions, i.e. in most cases by single high-energy collisions with helium. The four-sector instruments obviously are complex to operate. In addition to the three- and four-sector instruments, a number of hybrid sector-based MS-MS instruments have been developed, i.e. combination of a double-focusing sector instrument as the front-end and a quadrupole, an ion trap or a TOF analyser as the back-end. These hybrid instruments, such as the BE- q_{coll} -Q hybrid schematically drawn in **Figure 1b**, allow high-resolution precursor-ion selection, while collisions can be achieved in either the high-energy or the low-energy regime, i.e. in the third field-free region or in the quadrupole collision cell (RR4 in **Figure 1b**), respectively.

MS-MS in Triple-Quadrupole Instruments

A triple-quadrupole instrument (Q- q_{coll} -Q) consists of two quadrupole mass analysers, connected by means of a collision cell, which is an RF-only quadrupole device (**Figure 1c**). The mass analysers can be used for rapid scanning or selection in various MS-MS scan modes. The collision cell transmits virtually all ions irrespective of their m/z without separation of different m/z , enabling efficient collection and refocusing of the product ions generated by low-energy, multiple collisions with argon. Good sensitivity is achieved with such an instrument. Two-fold improvements in sensitivity can be achieved by replacing the RF-only quadrupole with hexapole or octapole collision cells. In addition, some manufacturers position the three quadrupole elements in a banana shape to reduce the collisions of neutrals on the detector, thereby reducing the background noise. The

Figure 1 Schematic diagrams of some MS-MS instrumentation: (A) double-focusing BE sector instrument, (B) hybrid BE- q_{coll} -Q instrument, (C) triple quadrupole Q- q_{coll} -Q instrument and (D) ion-trap instrument.

triple-quadrupole instruments are currently the most widely used instruments for MS-MS, although most instruments are used for routine quantitative bioanalysis in SRM mode after liquid chromatography (LC).

Recently, an extremely powerful hybrid Q-TOF system has been introduced, based on a quadrupole analyser as the front-end and a TOF analyser as the back-end (Q- q_{coll} -TOF geometry). As a result of the orthogonal geometry of the quadrupole and TOF, the TOF analyser enables high-resolution operation and thus accurate mass determination (up to 5 ppm), which can be extremely useful in structure elucidation by MS-MS, e.g. in peptide sequencing and impurity profiling.

MS-MS and MS-MSⁿ in Ion-Trap Instruments

MS-MS in an ion-trap instrument is fundamentally different from MS-MS in sector and triple-quadrupole

instruments. While in the latter the various stages of the process, i.e. precursor ion selection, CID and product-ion mass analysis are performed in different spatial regions of the instrument, in ion-trap instruments these stages are performed consecutively within the ion trap itself. It is 'tandem-in-time' rather than 'tandem-in-space' mass spectrometry. A simplified diagram of a 3D ion-trap system is shown in **Figure 1d**; new 2D (linear) implementations of ion-trap systems follow the same principles.

The measurement process consists of a series of steps: ions are either generated inside the ion-trap or injected into the trap from an external source. A suitable storage voltage applied to the ring electrode enables trapping of the ions generated or injected. Next, the precursor ion is selected by applying an ion isolation RF waveform voltage at the endcaps. At the same time the voltage on the ring electrode must be ramped to a new value to store

both the precursor ion and its product ions. Subsequently, CID is achieved by applying a resonance excitation RF voltage at the endcaps. This induces faster and more extensive ion trajectories in the trap, resulting in ion activation and subsequent fragmentation. The helium bath gas, present in the ion trap for stabilization of the ion trajectories, serves as the collision gas. In a normal product-ion MS-MS experiment, at this stage the product ions are scanned out of the ion trap towards the detector. However, the system also allows multiple stages of MS-MS, i.e. one of the product ions may be selected by means of an ion isolation RF waveform voltage at the endcaps, and subsequently activated and dissociated. This process can be performed up to ten times in current commercially available ion-trap systems, or as long as a sufficient number of ions remains; in practice, this typically allows four or five stages of MS-MS for most applications.

Compared with triple-quadrupole and especially with sector instruments, the ion-trap instrument provides more efficient conversion of precursor ion into product ions. However, the CID process via resonance excitation, although quite efficient in terms of conversion yield, generally results in only one (major) product ion in the product-ion mass spectrum. While with a triple-quadrupole instrument a series of product ions is observed, only one major fragment ion is observed with the ion trap. Other fragment ions are detected in the ion-trap system after multiple stages of MS-MS. The product-ion mass spectrum of the protonated triazine herbicide propazine described by Hogenboom and co-workers may serve as an example. In the spectrum from a triple-quadrupole instrument, the product ions are found at m/z 188, 146, 110 and 79. With the ion-trap instrument, three stages of MS-MS are required to observe all these ions, i.e. m/z 188 and a minor 146 in the first stage, m/z 146 in the second stage, and m/z 110, 104, 86 and 79 in the third stage. In this experiment, the most abundant product ion in each stage is selected as the precursor ion for the next stage. The fragmentation in the ion trap appears to be softer, or more controllable, than that in triple-quadrupole instruments. This stepwise fragmentation can be extremely useful in structure elucidation, but is a serious limitation in cases where confirmation of identity should be based on the detection of a number of particular product ions.

With the current commercial availability of various ion-trap MS-MSⁿ systems, equipped with an external ion source and for use in both GC-MS and LC-MS, MS-MS ion-trap systems can be expected to find more elaborate analytical applications.

MS-MS in Time-of-Flight Instruments

MS-MS in TOF instruments has only recently been reported by Kaufmann and Spengler. A reflectron-TOF

Figure 2 Schematic diagram of the procedure of MS-MS with post-source decay in a reflectron TOF instrument. Reproduced with permission of Masson éditeur and John Wiley & Sons from de Hoffmann E, Charette J, and Stroobant V (1996) *Mass Spectrometry, Principles and Applications*. Paris: Masson éditeur. Chichester: John Wiley & Sons.

should be used for MS-MS. While the ion activation may take place during ionization or even after ion acceleration, the actual fragmentation takes place after the ions have left the ion source (post-source decay). As a result, the precursor ions p and product ions d will have the same velocity, but different kinetic energy. Therefore, the MS-MS experiments can be performed in two steps, outlined in **Figure 2**: first, the instrument is operated in the linear mode, with the flight times of precursor and product ion being the same. Second, the instrument is operated in the reflectron mode. In this case, the precursor ion, having the higher kinetic energy, takes a longer path than the product ion. By comparison of the mass spectra from the linear and the reflectron mode, the fragment ions can be identified. Recently, it was also demonstrated that, via electrostatic ion manipulation of the ion beam, precursor-ion selection before post-source decay can be used. These approaches are extremely useful for the advanced mass analysis of ions generated by matrix-assisted laser desorption/ionization (MALDI).

An interesting approach to MS-MS is the combination of an ion-trap storage device and a reflectron time-of-flight instrument. While initially the ion trap was used only to store ions from the continuous ion source before the pulsed acceleration to the TOF analyser, it has recently been demonstrated by the group of Lubman that MS-MS in the ion trap before TOF mass analysis results in additional possibilities.

MS-MS in FT-ICR Instruments

In an FT-ICR instrument, which also is an ion-trapping device, MS-MS can be performed in a manner similar to

MS-MS in ion-trap instruments. However, fragmentation by collisions is generally much less effective because of the significantly lower pressures in the FT-ICR cell; this is only partially compensated for by the longer ion residence times that are achievable.

In both the quadrupole ion traps and the FT-ICR instruments, MS-MS in the product-ion scan mode is feasible, but other scan modes such as neutral-loss and precursor-ion scans are not possible.

Applications of MS-MS

Numerous applications of MS-MS have been reported in the literature, in which the MS-MS instrumentation is either used as a stand-alone instrument for sample introduction by a probe, or column-bypass injection in a liquid stream, or used in on-line combination with GC or LC. Especially in the latter area, where soft ionization strategies are frequently applied, MS-MS plays an important role. In this section, a number of applications of different MS-MS instruments are briefly reviewed. Most attention is focused on the analytical applications of MS-MS.

Fundamental Studies

The first studies with MS-MS concerned fundamental studies on the properties, structures and behaviour of gas-phase ions. This area continues to be important, as these fundamental studies lead to a better understanding of the processes involved in ion activation, fragmentation and CID. Fundamental studies can be subdivided into studies concerning the structures of ions in the gas phase, elucidation of reaction mechanisms and studies directed at obtaining thermochemical information from gas-phase species.

A currently important area of fundamental research in ion structures and reaction mechanisms, which also has significant analytical application, is the study of the fragmentation mechanisms of biomolecules in MS-MS. MS-MS is frequently applied to perform sequence analysis of biomolecules such as peptides, oligosaccharides and oligonucleotides. Fundamental studies are directed at elucidation of the formation of the various fragment ions observed, i.e. ions from backbone cleavages, side-chain specific ions and low mass ions such as immonium ions. In this respect, but also in other contexts, considerable research is directed at gaining a better understanding of the charge-remote fragmentations observed in the analysis of peptides, fatty acids and other compounds.

Structure Elucidation

MS-MS in the product-ion scan mode is generally quite successful in structure elucidation of unknowns. There

are ample examples available in the literature. However, the interpretation of the production mass spectrum is not always straightforward. When a protonated molecule is selected as precursor ion, the fragmentation rules significantly differ from the well-known fragmentation rules valid for molecular ions generated by electron ionization. Upon fragmentation, protonated molecules have a high tendency to rearrange and hydrogen shifts often take place. Knowledge of this type of fragmentation is less extensive and less systematically documented. Furthermore, the fragmentation in MS-MS may not result in a sufficient number of fragments to allow complete elucidation of the structure. In that case, additional strategies are required. In MS-MS studies with sample introduction via an electrospray interface for LC-MS, the combination of in-source CID and product-ion MS-MS of one of the fragment ions can be a useful tool to achieve further structure elucidation, as has been demonstrated, for example, by Bateman and co-workers for isomeric sulfonamides separated by capillary electrophoresis.

Because the experimental conditions for production mass spectra are strongly instrument dependent, generally not very well standardized and difficult to exchange between instruments from different manufacturers, there are at present no generally applicable spectral libraries for MS-MS spectra that can assist in structure elucidation problems.

Two recent instrumental innovations can be applied to further assist in the interpretation of product-ion mass spectra. As discussed above, the MS-MSⁿ capabilities of an ion-trap system allow the step-wise fragmentation of an analyte, facilitating the interpretation of the product-ion information and the fragmentation reactions involved. The use of a Q-TOF hybrid instrument allows accurate mass determination (at an accuracy of 5 ppm) of the product ions observed, which also facilitates the interpretation of the product-ion mass spectra.

Screening for Structurally Related Compounds

The combination of MS-MS and a soft ionization method is frequently applied in screening food or environmental samples for contaminants. The strategies involved are briefly illustrated with an example related to the detection of the sulfonamide antibiotic sulfamethazine (SDM) and its possible conversion products in meat samples.

In the product-ion mass spectra of protonated SDM and one of its expected conversion products (deaminosulfamethazine, DAS), a common peak at m/z 124 is observed,

Figure 3 Neutral-loss 123 Da mass spectrum obtained from the introduction of a sausage extract into a thermospray-MS-MS system. The peaks detected at m/z 200 and 215 were also present in the blank.

corresponding to the protonated aminodimethylpyrimidine. This ion is complementary to the ion from the phenyl- SO_2^+ group, found at m/z 141 for DAS and at m/z 156 for SDM. To screen meat samples for the presence of SDM and its conversion products, a neutral-loss scan was applied with a common loss of 123 Da, corresponding to the loss of the aminodimethylpyrimidine. This provides a highly selective screening method for SDM-related compounds: only those compounds in the meat extract that show the neutral loss of 123 Da are detected. The result for a sausage extract, shown in **Figure 3**, indicates that both SDM and DAS are present in the meat extract, as well as a compound with m/z 280, most likely a hydroxy analogue, and a monochloro compound with m/z 298, where the chlorine attachment is due to the brine used in production of the sausage. In this particular case, the use of the precursor-ion scan mode with m/z 124 as the common product ion would have been successful as well. However, for many compounds the charge is preferentially retained at only one part of the molecule, and in CID the part of the molecule with the most-favourable ionization properties will be observed as an ion in the product-ion mass spectrum, while the complementary part is lost as a neutral and thus not detected. For example, this is the case with protonated nucleosides: after CID only the protonated nucleobase is observed, while no fragment ions due to the sugar ring are observed. The neutral-loss scan mode is now applicable to screen for modifications of the base, while possible modifications of the sugar ring remain undetected. The complementary precursor ion scan is not applicable in this case.

Similar screening procedures may be applied to perform profiling of Phase II drug metabolites, i.e. based on the neutral-loss scan mode with a loss of 176 or 80 Da for glucuronide and sulfate conjugates, respectively.

Quantitative Bioanalysis

The use of MS-MS, especially in SRM mode, is an important application of MS-MS, especially in terms of

instrument sales. Triple-quadrupole instruments are most widely used for this purpose, in most cases in an online LC-MS combination. In developing the method, the MS-MS parameters are optimized in such a way that only one or two intense fragment ions are preferentially observed. These fragment ions are subsequently used in the SRM procedure, selecting the precursor ion in the first mass analyser and the fragment ion in the second mass analyser. By means of SRM, a specific reaction in the gas phase is monitored. By careful selection of an appropriate reaction, excellent selectivity can be achieved, and the analyte of interest can be analysed at low levels in complex matrices. This approach is especially useful in high-throughput quantitative bioanalysis, required to acquire pharmacokinetic and pharmacodynamic data of new drugs and their metabolites during drug developmental studies. In such studies, an isotopically labelled internal standard is applied. This internal standard preferentially shows the same neutral loss as the analyte of interest, enabling the detection of the analyte and the internal standard at two different m/z values in the SRM procedure.

Peptide Sequencing

A special application, used widely for 'bottom-up' proteomics, of structure elucidation by product-ion MS-MS is the sequence determination of amino acids in a peptide, which has been reviewed by Papayannopoulos. The low-energy CID of a protonated peptide in a triple-quadrupole instrument leads to a series of fragment ions that originate from backbone cleavages. The cleavage of the peptide bond primarily leads to either an acylium ion, when the charge is retained on the N-terminal side of the peptide, or a protonated peptide when the charge is retained at the C-terminal side of the peptide. According to the Roepstorff-Fohlmann nomenclature, these ions are indicated as b_n and y_n'' ions, respectively. The unknown amino acid sequence may be read from the two complementary series of ions in the product-ion mass spectrum. In high-energy CID, more advanced information can be obtained in peptide sequencing because, in addition to the backbone fragmentation, side-chain-specific fragment ions may be observed as well. This is especially important in the structure elucidation of isomeric amino acids, e.g. leucine and isoleucine. Given the extensive use of MALDI in peptide and protein mass analysis, the use of post-source decay processes to achieve peptide sequencing is of increasing importance.

Multiphoton excitation in mass spectrometry is determined by the characteristics of the applied light source (wavelength and intensity). One dominant feature therefore is spectroscopy. This concerns spectroscopy as a means of obtaining a species-selective ion source as well as mass selection for species-selective spectroscopy in a mixture. The latter leads to a rich manifold of techniques in many spectroscopic fields such as UV spectroscopy, cation and anion spectroscopy and photoelectron spectroscopy. Another dominant feature is photodissociation. Here multiphoton excitation allows variation from exceptionally soft ionization to very hard dissociation. It enables high yields of metastable decay products, which are particularly valuable for kinetic and energetic studies of molecular ions, a field of basic research in mass spectrometry. A third aspect is good compatibility with other techniques, e.g. chromatography or laser desorption, creating connections to different types of molecular systems (e.g. biomolecules) as well as to other analytical techniques. The last feature of multiphoton excitation dealt with in this article is options in analytical chemistry. The combination of speed, selectivity and sensitivity in a multiphoton ion source has great potential for environmental trace analysis or process integrated analysis of industrial production procedures, to name only two fields of application.

Multiphoton Excitation Schemes

In **Figure 1** different types of multiphoton excitation are schematically presented.

Figure 1a. Resonance ionization spectroscopy is performed by monitoring molecular ions while tuning the laser wavelength. If the energy of one photon is in resonance with a neutral electronic excited state, a

second photon is able to be absorbed, giving rise to an ion current peak. Thus, the neutral UV-absorption spectrum is transferred to the ion current which can be recorded mass selectively (in opposition to the absorption). Thus UV spectroscopy and mass spectroscopy are combined as a two-dimensional technique.

Figure 1b. Instead of a fixed mass window, the laser wavelength may be kept constant and in resonance with a specific transition of one molecule in a mixture (e.g. molecule M_A) but out of resonance with other molecules (e.g. molecule M_B). Thus, a species selective ion source is achieved. This is unique in mass spectrometry and particularly useful for trace analysis. In addition, by selecting particular intermediate states, molecular cations may even be formed in a few vibrational or rotational levels of the ionic ground state. This is a very valuable feature for studying molecular structure, reaction kinetics or spectroscopy of molecular ions.

Figure 1c. Additional excitation of the molecular ions takes place at increased laser intensities, where photon absorption (in the ion and fragment ion manifold) and dissociation processes to fragment ions follow each other. Owing to this 'ladder switching' the degree of fragmentation is tuneable from soft ionization (mainly or solely molecular ions) to hard ionization (mainly small or even atomic fragment ions). At appropriate laser wavelengths and intensities metastable decay processes may dominate the mass spectrum. Multiphoton excitation and dissociation is also possible with delayed laser pulses and at different positions in space, giving rise to new forms of tandem mass spectrometry.

Figure 1d. If a tunable laser is used for secondary excitation of molecular ions, resonance dissociation spectroscopy of molecular cations may be performed. Here excited cationic levels are subject to laser spectroscopy. They serve as intermediate states for the process of resonance enhanced multiphoton dissociation. This is quite similar to resonance ionization spectroscopy of neutrals. The difference is that a dissociation instead of an ionization continuum is finally reached by multiphoton excitation. The advantage of this technique is that it is independent of high ion numbers (as necessary for absorption spectroscopy), fluorescence [necessary for laser-induced fluorescence (LIF)] or predissociation and therefore is fairly general. In addition, mass selectivity is intrinsic and one may benefit from state selective ion

Figure 1 Different multiphoton excitation schemes applicable to molecular systems in the gas phase in mass spectrometry.

formation if resonance multiphoton ionization is used as an ion source.

Figure 1e. The degree of this state selective ion formation can be tested by analysing the kinetic energy of the emitted electrons while the laser wavelength is kept in resonance with the selected intermediate levels. This resonance enhanced photoelectron spectroscopy gives information about cationic ground states. It also helps in studies of the nature of the neutral intermediate states due to selection or propensity rules valid at the ionization and photoelectron emission process. A special, high-resolution version of photoelectron spectroscopy is zero kinetic energy photoelectron spectroscopy (ZEKE). If an intermediate excited state is involved, the first photon has to be kept in resonance with it while the second one is tuned over so-called ZEKE states very near to ionization thresholds. They end up in cationic states after field ionization. Instead of electrons, the cations may be recorded, allowing the option of mass selectivity.

Figure 1f. Finally, anion photoelectron spectroscopy (or photodetachment photoelectron spectroscopy) is discussed (although mostly a one-photon process). Owing to electron affinities being much smaller than ionization energies one photon absorption and detachment with lasers is possible for most anions. Either conventional photoelectron spectroscopy (**Figure 1f**) with a fixed laser wavelength or anion-ZEKE spectroscopy (similar but not equal to ZEKE) with tuned laser wavelengths is possible.

The intriguing feature of anion photoelectron spectroscopy is that it starts with ionic species (mass selection before spectroscopy) and ends up with neutral species (access to short-lived species, radicals, weakly bound molecular systems, traces in complex mixtures, etc.).

Experimental Realization in a Mass Spectrometer

In **Figure 2** several experimental setups are summarized in a hypothetical instrument that consists of a central part (neutral source, ion sources, mass separator, ion detector) and several options for a variety of multiphoton excitation experiments (see **Figure 1**). The neutral inlet system or source may be narrow tubing, for an effusive molecular beam, or a pulsed nozzle for supersonic molecular beams. The advantage of the former is its very simple and inexpensive construction. By placing the end of the tubing between the electrodes of the ion extraction optics (ion source II) high gas densities may be achieved at the position of laser ionization without too high a load on the vacuum system. Supersonic beams, on the other hand, allow efficient cooling of the internal degrees of freedom of molecular motion. Well-structured spectra of even larger molecules are thus achievable, containing rich spectroscopic information and enabling highly selective excitation and multiphoton ionization. Large

Figure 2 A hypothetical instrument that summarizes experimental arrangements where multiphoton excitation is involved.

involatile neutral molecules may be transferred into the gas phase by laser desorption. The insertion of a gas chromatographic capillary column in the neutral source even makes possible species selection before the gas inlet.

There exist a number of laser-induced techniques for ionizing these neutrals, such as resonance-enhanced multiphoton ionization (in ion source I or II, **Figure 1a** and **1b**), laser-induced vacuum UV ionization (e.g. at 118 nm from a 3×355 nm/Nd:YAG laser), electron attachment (in ion source I) and electron ionization (in ion source II). Electrons may be supplied by laser-induced photoelectron emission from metal surfaces, preferably from thin wires made out of material having a low work function (e.g. hafnium). Ions formed in source I have to drift into the ion optics of the mass spectrometer (together with the neutral molecular beam) and can be extracted by a pulsed electric field while ionization in source II may be performed within a static electric field with instantaneous ion extraction.

Extracted ions will enter the field-free drift region of a time-of-flight (TOF) mass separator. TOF mass analysers have turned out to be the ideal mass selection tools for pulsed laser-induced multiphoton excitation and ionization. A first mass selective detection may be performed in the so-called space focus of the ion source. Even for very short field-free drift regions (e.g. some 15 cm) a mass

resolution of 200 to 300 is possible in routine operations. A considerable enhancement of mass resolution is achieved by adding a special ion reflector with further field-free drift regions. In such a reflectron TOF analyser the ion cloud in the space focus (SF) is imaged onto the ion detector. This preserves the flight time distribution Δt , but extends the total flight time t , thus enhancing the mass resolution ($R_{50\%} = \frac{1}{2}t/\Delta t$).

Optional photoelectron spectrometers are included in **Figure 2**. These preferably are electric and magnetic field-free drift regions, allowing the analysis of electron kinetic energies by measuring electron flight times. They may be combined with ion source II for analysing photoelectrons emitted at resonance enhanced laser ionization (**Figure 1e**). A photoelectron TOF spectrometer can also be placed at the SF. Electrons due to photo-detachment of anions may then be analysed (**Figure 1f**). Since in the space focus masses are already separated, this kind of anion photoelectron spectroscopy is intrinsically mass selective. For neutral $\leftarrow$ cation photoelectron spectroscopy at ion source II, mass selection is only possible by additional photoion/photoelectron coincidence techniques.

In **Figure 2**, several laser beams are supposed to be used in combination or separately. By laser beam L1 resonance enhanced multiphoton ionization and

spectroscopy may be performed (Figures 1a and 1b). At higher intensities of laser L1, multiphoton dissociation additionally takes place (Figure 1c). Secondary multiphoton dissociation is possible by laser beam L2. Mass selective analysis of the manifold of secondary fragments results in tandem mass spectrometry. Recording the intensity of a selected fragment ion as function of laser L2 wavelength allows cation UV-visible spectroscopy (Figure 1d). Both experiments (tandem mass spectrometry or cation UV-spectroscopy) are also possible with laser beam L3 coupled into the SF. By the latter experimental arrangement considerably higher secondary mass selectivity is achieved, while the former arrangement may give better sensitivity. In addition, with laser L3 mass selective neutral $\leftarrow$ anion photoelectron (Figure 1f) and anion-ZEKE spectroscopy can be performed as mentioned above. Finally, laser beam L4 is used for photoelectron emission from a wire for anion formation by electron attachment. In addition, desorption of involatile neutral molecules into a supersonic molecular gas beam is performed with laser L4.

Resonance Multiphoton Ionization: Spectroscopy and Selective Ion Source

Mass selective laser excitation was applied originally for the UV and VIS spectroscopy of neutral molecules. However, the benefits of both mass selected UV spectra

and UV-resonance selective mass spectra were soon recognized.

In Figure 3 (right-hand side) the resonance ionization spectra recorded mass selectively (at 106 and 107 amu) show the electronic origin of the $S_1 \leftarrow S_0$ transition of *p*-xylene (106 amu) and its $^{13}\text{C}_1^{12}\text{C}_7\text{H}_{10}$ natural isotopomer. An isotopic blue-shift of $+2.7\text{ cm}^{-1}$ (corresponding to 0.02 nm) is found. On the left-hand side of Figure 3 two UV-resonance selected mass spectra are shown, resulting from resonance enhanced multiphoton ionization at 272.17 and 272.14 nm. The latter is the band centre of the 107 amu selective laser spectrum and clearly gives rise to a strong relative enhancement of the heavier mass in the mass spectrum.

An extraordinary impact on molecular UV spectroscopy (in particular of large molecules) has been brought about by supersonic beam cooling of internal molecular motions. The narrow line width in Figure 3 is due to this effect and allows isotopomer-selective ionization as illustrated in Figure 3. However, even for large involatile molecules well-resolved spectra with vibrational fine structure can be observed. To get these molecules into the gas phase, high temperatures or laser desorption were necessary. Figure 4 shows the spectra of heated gas samples containing dibenzo-dioxins seeded in argon gas and cooled in a supersonic molecular beam. For dibenzodioxins only their UV spectra in solution were known before the application of mass selective resonance ionization spectroscopy. On the left-hand side of Figure 4, the cold spectrum of unsubstituted dibenzodioxin is

Figure 3 Two options for resonance enhanced multiphoton ionization concerning ion source or spectroscopy: UV-resonance selected mass spectra (on the left) and mass selected molecular UV spectra (on the right) for *p*-xylene and its $^{13}\text{C}_1$ -isotopomers.

Figure 4 On the left: the cold (supersonic beam cooled) UV spectrum of dibenzo-dioxin measured via multiphoton ionization. On the right: the dichloro-congeners (with chlorine at the 3, 8, the 2, 8, and the 2, 3 positions) show similar well-structured spectra, giving wavelengths for congener selective ionization.

represented. Single vibronic bands of the $S_1 \leftarrow S_0$ transition appear, revealing low frequency 'butterfly' and torsional modes excited in S_1 . This and further arguments suggest a slight nonplanarity of dibenzodioxin in the S_0 and planarity of its S_1 and ionic ground state.

The combination of supersonic beams with mass selective spectroscopy has a further advantage. While mass selection allows discrimination against impurities, fragments and differently substituted (e.g. halogen, isotope) species, the high spectroscopic resolution enables the discrimination of structural isomers having the same mass. **Figure 4** clearly shows the significant difference of spectra of dibenzodioxins with two chlorine atoms substituted at symmetrically equivalent positions (i.e. the 2, 3, 7, and 8 positions). They differ only by their position relative to each other [e.g. neighbouring (bottom right) or not]. Wavelengths can easily be found (e.g. between 32 790 and 32 805 cm⁻¹) where these isomers may be ionized selectively. Spectroscopic studies of many different substituted aromatics have been performed. Effects such as increasing ionization energies with increasing degree of halogenation, decreasing energy of the S_1 state (e.g. below half the ionization energy) with increasing

molecular size and strongly differing lifetimes of the intermediate states have been experimentally observed or theoretically determined, and of course, these effects have to be considered for efficient ionization schemes.

Multiphoton Dissociation: Tuneable Fragmentation Ion Source

Species-selective ionization is one quality of multiphoton excitation in mass spectrometry. Another is the option to tune the degree of fragmentation from exceptionally low to very strong. The different possibilities of this feature are illustrated by the example of benzene in **Figure 5**. The variation of fragmentation is obtained by changing the laser intensity from 10⁷ W cm⁻² (corresponding to a UV-laser pulse with a 10 μJ pulse energy, a 10 ns pulse length and a 100 μm focus diameter) to 10⁹ W cm⁻². While the first mass spectrum is nearly free of fragments, the last mass spectrum consists mainly of carbon ions at mass 12. Both extremes cannot be achieved by conventional electron ionization or other ion sources and are unique for multiphoton excitation. It should be

Figure 5 Multiphoton dissociation of benzene at different laser intensities, inducing different degrees of fragmentation (from fragmentation-free at the top to dominating atomic fragment ions at the bottom of the figure). On the right of the spectra the model of 'ladder switching' is schematically displayed and explains the large variation of fragmentation by multiphoton absorption processes.

mentioned that these mass spectra have been taken with a short TOF mass spectrometer consisting only of three electrodes and one ion detector.

The reason for the astonishing feature of tuneable fragmentation is the specific excitation mechanism of multiphoton absorption in comparison with electron ionization which is a one-step process (the total energy is deposited in the neutral molecule in one step, causing ionization and fragmentation). Multiphoton ionization is due to consecutive absorption steps which are interrupted if fast decay channels are reached and are continued within the decay products (so-called 'ladder-switching'). Increasing the intensity increases the absorption probability (less time per absorption step), allowing the whole process to reach higher steps of the 'ladder of fragment ions' during the laser pulse. This process is indicated schematically in **Figure 5**. However, if very intense and very short laser pulses are used (i.e. femtosecond lasers), absorption is faster than decay and even ionization process and the total absorbed multiphoton energy is deposited in the molecule as a single event.

Since fragmentation is a rich source of information in mass spectrometry, this feature of multiphoton excitation may give a new impetus to this field of research. For example, increasing the laser intensity may allow one to tune for specific decay channels (e.g. breakage of bonds to functional groups, typical substituents or bonds within the molecular framework) and thus supply a low level but inexpensive type of tandem mass spectrometry. However, multiphoton excitation also allows access to the sensitive tool of metastable decay, the most informative source of fragmentation in mass spectrometry. While in conventional mass spectrometry considerable effort is necessary to study tandem mass spectra (mass separation before secondary collision-induced excitation), multiphoton excitation may create controlled ion decay dissociation (e.g. by enhancing specific metastable decay channels) very efficiently already in the ion source. This is illustrated and explained in **Figure 6**.

Here, part of a multiphoton ionization mass spectrum in the region around the benzene radical cation is represented. While the 'linear TOF' spectrum only reveals the molecular ion and its $^{13}\text{C}_1$ -isotopomer, the 'reflectron

Figure 6 Experimental demonstration (bottom) and schematic explanation (top) of the high yield of metastable decay products available with multiphoton dissociation.

TOF⁷ spectrum additionally shows the fragment ions $C_6H_5^+$ and $C_6H_4^+$ although the ion source conditions were identical. (The difference in mass resolution will not be discussed here, see the Further Reading section and other articles in this Encyclopedia.)

To understand this effect one should remember that product ions formed in the field-free drift region of a linear TOF instrument cannot be distinguished from their parent ion (same ion velocity). A reflectron TOF mass analyser, however, corrects for ion kinetic energy deviations and shows all fragment ions of the same mass independent of their ion kinetic energy (at least for an energy mismatch of $\pm 10\%$) at the same flight time. Thus **Figure 6** demonstrates the existence and high yield of metastable decay induced by multiphoton excitation (in **Figure 5** the total fragmentation yield was small, main peak was $C_6H_6^{*+}$). An explanation for this is given at the top of **Figure 6**. By resonance enhanced multiphoton ionization, molecular ions M^{*+} with small internal energy and a narrow energy distribution ΔE are produced (soft ionization, no absorption in the ion). The absorption of a further photon in the molecular ion M^{*+} will then result in excited ions which still have a narrow energy distribution ΔE^* . If the photon energy is in the range of the energy interval between the ion ground state and the threshold of a decay channel then the overlap of the metastable decay region (near F^+ decay threshold) and internal energy distribution ΔE^* will be large. In contrast to multiphoton excitation, electron ionization is usually performed with 70 eV electrons, resulting in a broad internal energy distribution whose overlap with the metastable decay range is relatively small (few metastable decay products). The special features of multiphoton excitation concerning metastable decay have initiated a renaissance of ion kinetic decay studies.

Instead of a single colour excitation (laser L1, **Figure 2**) a second laser (L2 or L3) can be used. Secondary multiphoton excitation is then possible, which can be performed with different laser wavelengths, at different positions and different times from that of the ionizing laser L1. Thus, selective secondary excitation of a group of fragments (e.g. with L2 in ion source II) or even of single product ions with one well-defined mass (e.g. with L3 in the SF) is possible. This already is an approach to highly sophisticated tandem mass spectrometry with the benefit of well-defined internal ion energies and a high yield of secondary fragmentation. In **Figure 7**, a primary multiphoton mass spectrum of benzene and secondary mass spectra of four different fragment ions are shown. This experiment has been performed to elucidate multiphoton fragmentation and is shown here to illustrate its tandem mass spectrometry option. The primary mass spectrum is due to a laser wavelength of $\lambda_1 = 258$ nm (absorption maximum of benzene), while the secondary mass spectra of C_4^{*+} , C_4H^+ and $C_4H_2^{*+}$ have been performed with $\lambda_3 = 355$ nm. The $C_4H_3^+$ fragment does not show fragmentation at $\lambda_3 = 355$ nm and has been excited with $\lambda_3 = 266$ nm. Furthermore, C_4H^+ does not exhibit a secondary C_4^{*+} product ion as $C_4H_2^{*+}$ and $C_4H_3^+$ although it dissociates at 355 nm. These effects

Figure 7 Primary and secondary mass spectra of benzene, illustrating the options of multiphoton excitation for tandem mass spectrometry.

already indicate a complex multiphoton fragmentation tree with several decay channels. It is not the task of this article to go into more detail of that specific process, rather this example should illustrate the available options of multiphoton excitation for tandem mass spectrometry.

Multiphoton Excitation for Mass Selective Ion Spectroscopy

There are several options for the use of multiphoton excitation for ion spectroscopy. One is resonance enhanced photoelectron spectroscopy. In contrast with conventional photoelectron spectroscopy, where single VUV photons

are used, a neutral excited intermediate state is involved which allows the application of the low energy UV-photons available with lasers. Owing to small excess energies, the ionic ground state is most often studied by this technique. The involvement of different vibronic intermediate states results in a variation of the photoelectron spectrum and is a valuable means for obtaining additional information about the character of ionic and even of neutral intermediate states. Resonance enhanced photoelectron spectroscopy cannot be performed in a truly mass selective way. Either the neutral source consists only of one sort of molecule (which can be checked by synchronously observing the produced molecular ions) or photo-ion photoelectron coincidence spectroscopy is performed. But

the high-resolution version of resonance enhanced photoelectron spectroscopy, ZEKE spectroscopy, can be performed in a true mass selective mode. Both methods are beyond the scope of this article (for further information, see the Further Reading section).

In addition to the study of the ionic ground state, resonance enhanced photoelectron spectroscopy allows one to characterize multiphoton ion sources with respect to the internal energy distribution of the produced ions. For favourable cases it even may supply information as to how to achieve state selective ion production. The example of fluorobenzene has been chosen in **Figure 8** to illustrate resonance enhanced photoelectron spectroscopy as well as further types of ion spectroscopy involving multiphoton excitation.

At the bottom of **Figure 8** the resonance ionization spectrum of fluorobenzene (cooled in a supersonic beam) is shown, exhibiting the electronic origin 0_0^0 as well as other vibronic transitions (e.g. excitation of one quantum of the $6b$ -vibration). In the middle of **Figure 8**, two photoelectron spectra are presented which involve different neutral intermediate states. A significant difference is observed, indicating that the excitation of the vibrationless S_1 or of the $6b$ -mode in the S_1 induces different populations in the molecular ion. This supports assignments in the photoelectron spectrum and allows production of state-selected fluorobenzene ions for further experiments (ion kinetics, ion spectroscopy).

Such a secondary experiment is displayed at the top of **Figure 8**. After production of fluorobenzene radical cations via resonance enhanced multiphoton ionization, preferentially in the ionic ground state, multiphoton dissociation spectroscopy has been applied. However, in contrast to **Figure 1d**, an even more elaborate excitation scheme has been used here, exploiting the experimental options of TOF mass spectrometry. Laser L2 (ion source II) is used solely for spectroscopy; laser L3 (SF) is responsible for detection by multiphoton dissociation. The benefit of this scheme is that laser L2 can be optimized for spectroscopy while dissociation by laser L3 is highly mass selective, efficiently suppressing background signals from other molecular or fragment ions. Using modern double-pulse lasers, the requirements for the laser system and mass analyser are still reasonable. The result is a very well-resolved ion spectrum. One should keep in mind that in the case of fluorobenzene, as for many other halogen-substituted and the non-substituted benzene cations, fluorescence spectroscopy is not possible (to say nothing about absorption spectroscopy) and only low-resolution conventional photoelectron spectra exist.

When treating ion spectroscopy one should not forget anions. Similar spectroscopic techniques may be used as for cation spectroscopy. For instance, dissociation spectroscopy is also possible for molecular anions. Since excited anionic electronic states mostly do not exist, one

uses infrared multiphoton dissociation to study vibrational levels of the ground state. Another interesting technique is the photo-electron spectroscopy of anions

Figure 8 Multiphoton excitation and ion spectroscopy: Bottom spectrum: cold, mass selected UV spectrum ($S_1 \leftarrow S_0$ transition) of fluorobenzene, providing wavelengths for efficient and selective ionization. Middle spectra: photoelectron spectra induced by UV-resonance enhanced two-photon absorption. Choosing different intermediate states [$S_1(0,0)$ or $S_1(6b^1)$] results in different populations of the final fluorobenzene radical cations. Top spectrum: spectroscopy of the excited ionic state of the fluorobenzene radical cation measured by multiphoton dissociation spectroscopy. The ions have been prepared via the neutral 0_0^0 transition. A special excitation scheme has been used to optimize cation spectroscopy (for further details see text).

(photodetachment photoelectron spectroscopy), which exhibit a very specific feature. This technique differs from cation $\leftarrow$ neutral photoelectron spectroscopy in two respects: (i) the final state is a neutral one; thus anion photoelectron spectroscopy delivers information about neutrals rather than ionic systems. (ii) The initial state is anionic; thus mass selection before spectroscopy is possible. As a result, mass selective spectroscopic information

of neutral molecular systems is supplied which otherwise is not accessible. This is of particular interest for neutral systems which are only available in complex mixtures or are short-lived intermediate reaction products or radicals.

One example is shown in **Figure 9**. Metal-carbon-hydrogen complexes are of great importance as intermediates in heterogeneous catalytic reactions of

Figure 9 Anion photoelectron spectroscopy. Its unique features are (i) intrinsic mass selectivity and (ii) neutrals as final states. Here, as an example the results for compounds of iron, carbon and hydrogen are shown which exist in catalytic processes, high-temperature terrestrial or low-temperature astrophysical chemistry. Bottom spectrum: a primary anion mass spectrum containing anions of the complexes of interest. Top spectra: anion photoelectron spectra obtained by electron kinetic energy analysis after laser-induced photodetachment. They reveal the change of molecular structure and electronic energies for increasing numbers of hydrogen atoms in the complex.

hydrocarbons on metal surfaces, but are not available as pure samples. At the bottom of **Figure 9** an anion mass spectrum of such complexes is presented. These complexes have been formed by a gas phase reaction in the high density region of a supersonic molecular beam (acetylene seeded in argon). Iron atoms as well as low-energy electrons are supplied by laser ablation from an iron wire which is positioned as near as possible to the nozzle of the supersonic beam valve. Clearly, FeC_iH_n^- complexes appear in the spectrum together with carbon and carbon hydride clusters. Mass selected anion photoelectron spectra which supply information about the neutral complexes FeC_2 , FeC_2H and FeC_2H_2 are presented at the top of **Figure 9**. Obviously, an increasing hydrogen content of the complex results (i) in a decreasing electron affinity (transition to state X), (ii) in a smaller change of molecular structure (Fe–C distance) between anion and neutral (Franck–Condon envelope of the Fe–C stretching frequency) and (iii) in a strong decrease of energy gaps between higher electronic states (X, A, B, C) (a preliminary assignment in the case of FeC_2H_2). Although anion photoelectron spectroscopy is mostly due to a one-photon process, it has been considered here to show the large variety of experimental possibilities when combining laser excitation and mass spectrometry.

Combination of Multiphoton Excitation with Other Neutral Sources: Laser Desorption

Since multiphoton excitation in mass spectrometry takes place in the more or less tight laser focus, which can easily be shifted in space and time or be subject to other variations, it can be combined with different ion optical or mechanical arrangements (e.g. sources of neutral molecular systems) without the need for much additional hardware. Thus, by combination with chromatography (particularly gas chromatography), species selection has successfully been realized. Another very promising combination, which has frequently been applied in the recent past for the study of involatile molecules (e.g. polycyclic aromatics, biomolecules), is that of laser desorption of neutral molecules and resonance enhanced multiphoton ionization. All the benefits of multiphoton mass spectrometry, such as soft ionization, selective ionization, controllable fragmentation or secondary excitation for tandem mass spectrometry, may be used in this field.

In **Figure 10**, the example of a biologically relevant molecule is displayed. Porphyrins containing central metal atoms (e.g. Mg or Fe) represent the molecular frame of important biomolecules such as chlorophyll or haemoglobin which mainly differ in their central metal atom and specific side-chains. In **Figure 10**, the TOF mass spectrum of zinc mesoporphyrin-IX dimethyl ester

is shown, revealing a small degree of fragmentation. Inset A displays the molecular ion on an expanded mass scale and nicely reveals the typical isotopic pattern of Zn convoluted with that of ^{13}C -isotopomers (at the used wavelength of $\lambda_1 = 280\text{ nm}$ and the internal molecular temperature of $\geq 300\text{ K}$, ionization is not isotope selective). The fragment peaks near 155 u consist of a narrow peak ($M^+ - 64$) and a group of peaks ($> M^+ - 73$). The latter results from the loss of a side-chain (Zn-isotope pattern preserved) while the former arises from the loss of the central Zn atom (no Zn-isotope pattern remains). It shows a nearly identical isotope pattern (owing to ^{12}C – ^{13}C distribution) to the mesoporphyrin-IX dimethyl ester without a central atom, whose molecular ion is shown in inset B of **Figure 10**.

Multiphoton Mass Spectrometry for Chemical Trace Analysis

Both the high species selectivity and the soft ionization make resonance enhanced multiphoton excitation an excellent ion source for chemical trace analysis. In addition, the use of pulsed lasers combined with TOF mass spectrometry (also a pulsed technique) enables the recording of single mass spectra within a few milliseconds, depending on the repetition frequency of the laser pulses (typically 20 to 50 Hz). The unification of high speed, selectivity and sensitivity indicate that multiphoton mass spectrometry will become firmly established in the highly sophisticated analytical technology of the future. In **Figure 11**, the variety of applications is illustrated by examples from different fields, namely raw gas analysis of a waste incinerator, research for health care, production integrated analysis in the food industry and exhaust trace analysis of motor cars.

In **Figure 11a** (incinerator), traces of naphthalene (sub-ppb range) in the raw gas of a pilot waste incinerator have been recorded over 900 s. During this time a major failure of the combustion process (at 500 s) which gave rise to an increased concentration of polycyclic aromatics by many orders of magnitude has been studied. This event was preceded by small but significant fluctuations of the naphthalene concentration, which were only detectable by a fast, but nevertheless selective and sensitive, method. Effects like these could be used in future for online control of incinerator plants. This could help to improve pollutant emission by reducing their formation rather than retaining them after the combustion process by expensive cleaning procedures. An example of even more direct health care research is shown in **Figure 11b** (cigarette smoker). Here the xylene content in air recorded in the mouth space of a cigarette smoker is recorded. The 50-fold expansion of a single puff demonstrates the high temporal resolution of less than 0.1 s.

Figure 10 The combination of neutral laser desorption and resonance enhanced multiphoton ionization. A TOF mass spectrum of zinc mesoporphyrin-IX dimethyl ester is presented. Inset A: the isotopic pattern (zinc, carbon) of the molecular ion. Inset B: the molecular ion of mesoporphyrin-IX dimethyl ester (TOF mass spectrum not shown) which displays the same isotope pattern as peak (M-64) due to loss of a zinc atom.

The next spectrum shows fluctuations of caffeine concentration in the headspace above one single green coffee bean which has been suddenly heated up to high temperatures (far above typical roasting temperatures). The very short spikes of caffeine emission are induced by CO_2 (pyrolysis product) causing distinct cracks of the plant skin. At the single ejection events solvated caffeine is swept along with the CO_2 . Of course, other molecular components (e.g. those which are used as indicators for the progress of coffee roasting) can be monitored thus enabling online control of the roasting process.

In **Figure 11** (automobile), the behaviour of acetaldehyde (a dehydrogenation product of ethanol which is typical for incomplete combustion) and nitric oxide in the exhaust of a motorcar is recorded during the first seconds of a cold engine start. Unleaded gasoline containing 10% of ethanol has been used as fuel. Both pollutants strongly support the formation of ozone in the troposphere (e.g. smog in large cities). Their reduction, e.g. by an electronically improved regulation of the motor, is therefore of major interest. Thus, the highly dynamic processes in combustion engines must be

studied, but appropriate fast analytical techniques are not yet commercially available. In **Figure 11d** five different situations initiated by distinct fast events of the motor regulation can be recognized. From 0 to 2 s, no combustion is active and none of the two pollutants are emitted. At time (1), ignition starts, causing a high peak of the combustion product NO which drops off to a level of some 100 ppm. At time (2), a fuel-rich mixture is injected for a better start of the engine. A sudden increase of acetaldehyde is observed, indicating incomplete combustion due to a shortage of oxygen. At time (3), the speed of idle running is reached (faster in a newly started engine for stabilization of the combustion) and the fuel is changed to a lean mixture. Acetaldehyde, the product of incomplete combustion drops instantly, while NO, the product of complete combustion, increases strongly again. However, heavy fluctuations of NO still indicate some instability of the whole process. After stabilization (NO level now at 80 to 100 ppm) the idle running frequency is reduced to the regular speed at time (4). The NO level drops significantly, but a slight increase and then a gradual decrease of acetaldehyde is observed. This is consistent with a reduced combustion temperature at

Figure 11 Several examples of applications of multiphoton ionization mass spectrometry for chemical analysis. (a) Incinerator: traces of naphthalene have been recorded in the raw gas of a pilot waste incinerator. Here a major failure of the combustion and preceding fluctuations of the naphthalene concentration were studied. (b) Cigarette-smoker: the xylene concentration in the mouth space of a cigarette-smoker. (c) Single coffee bean: a single coffee bean has been heated to untypically high temperatures. Single short ejection events of caffeine have been observed due to distinct cracks of the plant skin of the coffee bean. (d) Automobile exhaust: acetaldehyde due to incomplete combustion and NO (complete combustion) during the starting of a cold engine measured in the exhaust. Different behaviour is observed when the ignition is starting (1), the fuel mixture becomes rich (2) and lean (3) and the speed of idle running is reduced to its regular frequency (4).

lower speed and desorption of fuel from the walls of the injection system for about half a second.

Symbols

B	rotational constant
E_i	ionization limit
h	planck constant
J	rotational quantum number
n	principal quantum number
$\hat{O}$	multiphoton transition operator
R	Rydberg constant
$T_q^k(\hat{O})$	q th component of the tensor of rank k representing $\hat{O}$
δ	quantum defect
ε	electric vector
ν	frequency
v	vibrational quantum number
$\tilde{\nu}$	wavenumber

Multiphoton spectroscopy involves the excitation of an atom or molecule from one electronic state A to another B by absorption of two or more photons in contrast to more conventional spectroscopies that involve just a single photon. We identify two distinct variants of multiphoton spectroscopy. **Figure 1a** depicts a sequential multiphoton absorption, i.e. an incoherent multiphoton

excitation proceeding via successive allowed one-photon transitions:

where the two photons may have the same (or, more generally, different) frequencies. Such schemes provide the basis for a wide range of double-resonance spectroscopies. By way of contrast, **Figure 1b** illustrates the simultaneous (i.e. coherent) absorption of two photons without the involvement of any resonant intermediate state M. The realization that an atom or molecule could undergo such coherent multiphoton excitation dates back to the early days of quantum mechanics, but the experimental demonstration of such multiphoton excitations had to await the advent of the laser to provide the necessary very high light intensities required to compensate for the inherently low multiphoton transition cross sections. With a conventional light source, a two-photon excitation might be 10^{20} times less probable than a one-photon absorption, but the I^2 intensity dependence combined with the $>10^{12}$ increase in power density available with lasers makes such transitions relatively straightforward to observe with modern pulsed lasers. The fraction of photons absorbed will always be small, so identifying that a multiphoton excitation has occurred almost always involves monitoring some consequence of the multiphoton excitation rather than observing the absorption itself. Three of the more common consequences are depicted in **Figure 1b**. If the excited state B fluoresces, the multiphoton excitation spectrum can be obtained simply by monitoring the (multiphoton) laser-induced fluorescence (LIF) as a function of excitation wavelength. Given the high light intensities required to drive the multiphoton absorption step, however, it will generally be the case that some of the molecules excited to state B will absorb one (or more) additional photons and ionize. This is termed resonance-enhanced multiphoton ionization (REMPI), and is the most widely used method for detecting multiphoton absorption by gas-phase species. The third possible process for the excited state, dissociation (or any other loss mechanism), will reduce the photons or ions detected, and is a potential limitation that is discussed further below. The other important condition is that the $B \leftarrow A$ two-photon (or multiphoton) excitation has a nonzero transition

Figure 1 Illustration of (a) sequential and (b) simultaneous two-photon excitation from state A to state B. Also shown in (b) are three possible fates of the excited state B: fluorescence, dissociation and further photon absorption that ionizes the molecule. This latter process is termed 2 + 1 resonance-enhanced multiphoton ionization (REMPI).

probability; the selection rules depend on the number of photons and the differences between one- and two-photon transitions have many analogues with those distinguishing infrared and Raman vibrational spectroscopy. If the selection rules are satisfied, then the spectrum obtained by measuring the ion yield (or the yield of the accompanying photoelectrons) as a function of excitation wavelength will provide a signature of the $B \leftarrow A$ two-photon transition of the neutral molecule; analysis can provide structural (and, in some cases, dynamical) information about the excited state B.

Multiphoton Selection Rules

As in one-photon spectroscopies, symmetry is crucial in determining multiphoton transition probabilities. A multiphoton transition between two states A and B is 'allowed' if the transition moment $\langle A | T_q^k(\hat{O}) | B \rangle$ is nonzero; i.e. if the product of the irreducible representations for the wavefunctions of state A and B and that of $T_q^k(\hat{O})$ – the q th component of the spherical tensor of rank k representing the multiphoton transition operator $\hat{O}$ – contains the totally symmetric representation. Symmetry considerations ensure that only spherical tensors of either odd or even rank will contribute to any one-colour multiphoton excitation. Thus, for example, whereas one-photon electric dipole transitions must be carried by components of rank 1, only components of rank $k=0$ and/or $k=2$ can contribute to two-photon transitions brought about using photons of identical frequency and polarization. The $k=0$ component (a scalar) can only contribute to a two-photon transition connecting states of the same symmetry. Identification of $k=0$ components in two-photon excitation spectra is generally rather straightforward since they are forbidden (and 'thus disappear') when the spectrum is recorded using circularly polarized light. Sensitivity to the polarization state of the exciting radiation is one important feature distinguishing one-photon and multiphoton transitions. As **Tables 1** and **2** show, for all but the least symmetric molecules, at least some of the $k \neq 1$ components will span representations different from (or additional to) those of the one-photon electric dipole moment operator.

Multiphoton excitations can thus provide a means of populating excited states via transitions that are 'forbidden' in traditional one-photon absorption spectroscopy. Two-photon spectroscopy has proved to be particularly valuable in this regard, especially in the case of centrosymmetric molecules, e.g. H_2 , N_2 , O_2 , the halogens, ethyne and benzene. All of these molecules have *gerade* ground states. Thus, in each case, one-photon absorption provides a route to populating the *ungerade* excited states but the *gerade* excited states are inaccessible unless the

excitation is carried out using an even number of photons. Further inspection of **Table 1** hints at the increased complexity of coherent multiphoton excitation spectra. While governed by the same spin-conservation requirements and vibrational (i.e. Franck–Condon) restrictions as one-photon spectra, an n -photon excitation can support changes in rotational quantum number $\Delta J \leq n$.

Experimental Methods

The 'basic' multiphoton excitation experiment simply involves focusing tuneable laser radiation into a cell containing a low pressure (typically a few torr) of the atomic or molecular gas of interest and observing the resulting laser-induced fluorescence or, more commonly, the resulting ions or electrons (in the case of REMPI detection). In the latter experiment, the cell will typically be equipped with a pair of biased electrodes: an MPI spectrum is obtained simply by measuring the total ion, or the total photoelectron, yield as a function of excitation wavelength. The structure appearing in such a spectrum will reflect the resonance enhancements provided by the various rovibrational levels of the resonant intermediate electronic state(s) of the neutral, and may be analysed to provide spectroscopic (and thus structural) information about the excited neutral molecule. This 'basic' form of the REMPI experiment has limitations, and much of the recent experimental effort has been directed at improving both the selectivity and sensitivity of the technique.

One deficiency of this basic style of REMPI experiment is that all ions will be measured, irrespective of their masses, or that all photoelectrons will be counted, irrespective of their kinetic energies. A molecular MPI spectrum recorded in a static cell could therefore well include superimposed features associated with REMPI of the parent of interest, of neutral fragments arising from unintentional photodissociation of the parent molecule and of any other species present in the sample. Such potential ambiguities can usually be resolved by mass-resolving the resulting ions, and in most contemporary REMPI experiments this is achieved by time-of-flight (TOF) methods using either a linear TOF mass spectrometer or a reflectron TOF mass spectrometer to provide enhanced resolution. A variety of fast charged particle detectors can be used, together with suitable time-gated signal-processing electronics, to monitor the REMPI spectrum associated with formation of any single, user-selected, ion mass. In this way it is usually possible to distinguish spectral features associated with the parent from those arising from REMPI of neutral photofragments, or to distinguish different isotopomers of the same parent. Mass-resolved REMPI spectroscopy necessarily requires use of collision-free conditions; the

Table 1 Allowed changes in some of the more important quantum numbers and symmetry descriptors for atoms and molecules undergoing one-colour multiphoton transitions involving one ($k=1$), two ($k=0$ and 2) and three ($k=1$ and 3) photons

^aAssuming Hund's case (a) or (b) coupling. Ignore u/g labels for non-centrosymmetric linear molecules.

^b A_1' and A_2'' reduced to A_1 , A_2' becomes A_2 , and E' and E'' both transform as E in C_{3v} molecules.

precursor of interest in such experiments is thus introduced into the mass spectrometer source region as a molecular beam.

It often proves useful to measure the kinetic energies (KEs) of the resulting photoelectrons also. Such measurements also require use of a molecular beam so that

their KEs (which are usually measured by TOF methods in a spectrometer designed to minimize stray electric and magnetic fields) can be recorded under collision-free conditions; they provide the basis for a number of variants of photoelectron spectroscopy discussed below.

Applications

Less restrictive selection rules are just one of several benefits that can arise when using multiphoton excitation methods. Experimental convenience is another. A multiphoton excitation using visible or near-ultraviolet (UV) photons can often prove the easiest route to populating an excited state lying at energies that, in one-photon absorption, would fall in the technically much more demanding vacuum ultraviolet (VUV) spectral region. Other benefits derive from the fact that multiphoton excitations normally require the use of a focused pulsed laser because of the small excitation cross section. The interaction is thus concentrated in a localized volume (the focal volume). The technique is therefore highly suitable for spatial concentration profiling, and well matched for use with supersonic molecular beams; many previously impenetrable molecular spectra have been interpreted successfully after application of multiphoton excitation methods to jet-cooled samples of the molecule of interest. This can be a huge benefit, especially in the case of REMPI where the resulting particles are charged

and can be collected with far higher efficiency than could, for example, laser-induced fluorescence (LIF) from the excited state B. This benefit not only manifests itself in high sensitivity but, as we have seen, also offers additional species selectivity by allowing both mass analysis of the resulting ions and KE analysis of the accompanying photoelectrons.

Spectroscopy, Structure and Dynamics of Excited State Species

REMPI spectroscopy is typically used to probe high-lying electronic states, for which dissociation is always likely, but it will discriminate in favour of the more long-lived states because of the competition between ionization and dissociation (as in **Figure 1b**). There is one class of excited states that are often relatively long-lived rydberg states, which thus tend to dominate REMPI spectra. Molecular Rydberg states are conveniently pictured as a positive ion core, consisting of the nuclei and all but one of the valence electrons, with the remaining valence electron promoted to a state with a high principal quantum number, n . Such orbitals are large, spatially diffuse, and hence nonbonding, and are known as Rydberg orbitals. This is because the physical picture is very similar to that in the hydrogen atom, and the energy levels follow a modified Rydberg formula:

$$\bar{\nu} = E_i - \frac{R}{(n - \delta)^2} \quad [2]$$

where R is the Rydberg constant. As written, $\bar{\nu}$, E_i and R must have the same units. E_i is the ionization limit of the ion core and δ is known as the quantum defect. It provides an indication of the extent to which the wavefunction of the Rydberg electron penetrates into the core region and its value is found empirically to be fairly constant for a given type of orbital. For molecules composed entirely of first-row atoms, typical values are $\delta = 1.0$ – 1.5 for s orbitals, $\delta = 0.4$ – 0.8 for p orbitals and $\delta \sim 0$ for all higher functions. Such qualitative ideas can be very useful for interpreting the patterns of excited states observed in many families of polyatomic molecules, though modifications due to configuration interaction (i.e. mixing between zero-order states sharing a common symmetry species but arising from different electronic configurations) can complicate such simple expectations. **Figure 2**, which shows a $2 + 1$ REMPI spectrum of the NH radical, serves to demonstrate several of these points. The spectrum is obtained by linearly polarized simultaneous two-photon absorption (at wavelengths ~ 271.2 nm) of NH radicals in their low-lying metastable excited $a^1\Delta$ state, followed by further one-photon excitation and detection of ions with m/z 15. Rotational analysis confirms that the spectrum is carried by a two-photon transition, linking states of $^1\Delta$ (lower state) and $^1\Pi$

symmetry, while the observation of neighbouring vibrational bands (including hot bands originating from the $v = 1$ level of the $^1\Delta$ state) verifies that this is an electronic origin band. Changes in rotational quantum number $\Delta J \leq 2$ are clearly evident, as anticipated in **Table 2**. Knowing the ionization limit of the NH radical ($108\,804 \pm 5$ cm $^{-1}$, measured relative to the $X^3\Sigma^-$ ground state), we can deduce a value for the quantum defect of this state ($\delta = 0.79$) which, taken together with its known symmetry, suggests that this transition should be associated with electron promotion from the highest occupied doubly degenerate 1π orbital (the little-perturbed $2p_x$ and $2p_y$ orbitals of atomic N) to a $3p\sigma$ Rydberg orbital. The spectrum appears red-degraded, indicating a 13% reduction in the effective B rotational constant upon electronic excitation. Multiphoton rotational line strengths (the multiphoton analogues of the Hönl–London line strength factors applicable to one-photon spectra) may be calculated, allowing derivation of the relative populations of the various initial quantum states contributing to the spectrum.

The simulated S branch contour shown in the top left part of **Figure 2** serves to illustrate another possible application of REMPI spectroscopy. Closer inspection of the experimental spectrum reveals that all transitions involving excited state levels with rotational quantum number $J' = 7, 8$ or 9 appear anomalously weakly. This is due to a very localized predissociation of the $v = 0$ level of the $f^1\Pi$ state of the NH radical. For these rotational levels in particular, the $f^1\Pi$ state predissociates at a rate that is comparable to, or greater than, the ionization rate; this competition leads to reduced ionization probability and a relative diminution of the eventual ion yield; multiphoton excitations proceeding via such predissociated levels thus appear with reduced relative intensity in the REMPI spectrum. In extreme cases the transitions involving such predissociated excited levels may show lifetime broadening as well. Clearly, in the case of more heavily predissociated excited states the REMPI signal is not only weaker (and thus harder to detect), but also less resolved, because of the increasing overlap of neighbouring lifetime-broadened spectral lines.

Figure 3 shows an example involving the SO radical where the predissociation is so severe that an alternative detection scheme must be used. The necessary two-colour sequential double-resonance excitation scheme is indicated in the figure; the first step is designed to populate a single rotational level in the $A^3\Pi$ state. The fluorescence from this state is monitored, and a drop is seen when the second laser is tuned to a frequency appropriate for further excitation of these state-selected molecules to the $D^3\Pi$ state. **Figure 3** shows the A state fluorescence intensity as the second laser is scanned, and reveals a very broad Lorentzian peak (50 cm $^{-1}$ full-width half-maximum). Use of the energy–time form of the

Figure 2 Two-photon resonant MPI spectrum of the origin band of the $f^1\Pi \leftarrow a^1\Delta$ ($3p\sigma \leftarrow 1\pi$) transition of the NH radical obtained using the excitation scheme shown at the top left and monitoring the m/z 15 ion mass channel as a function of the laser wavelength. Individual line assignments are indicated via the combs superimposed above the spectrum. The simulation of the S branch (top right) highlights lines that appear in the experimental REMPI spectrum with reduced intensity because of competing predissociation.

Figure 3 A two-colour fluorescence depletion spectrum of one rovibronic line associated with the $D^3\Pi \leftarrow A^3\Pi$ transition in SO. The two-colour excitation scheme used (upper right) is required because of the very short lifetime (100 fs) of the $D^3\Pi$ state. This results in the linewidth of 50 cm^{-1} shown in the spectrum.

uncertainty principle allows determination of the excited state lifetime (100 fs) from the width of the measured line shape. The D state is notionally a $4s\sigma$ Rydberg state, and its short lifetime is presumably indicative of significant mixing with a valence state, since the D state is the lowest-lying Rydberg state in SO.

This is just one of many instances where two-colour, double-resonance multiphoton spectroscopy can of great help in providing additional spectroscopic, structural and dynamical information about the excited states of small and medium-sized gas-phase molecular species. **Figure 4** shows the opposite extreme, where the final state is long

Figure 4 Two-colour ionization spectrum exciting levels of a ${}^3\Pi_g$ ion pair state of S_2 , using the scheme shown in the inset. Note that a two-step process is required, both to give a net $g \leftarrow g$ excitation and to overcome the poor Franck–Condon factors for the transition.

lived (and ionization is used to detect that the multiphoton absorption has occurred), but double resonance is required to reach the states at all. The example involves states of the S_2 radical lying at energies around $75\,000\text{ cm}^{-1}$ where, without the simplification of jet cooling and the additional state selectivity afforded by double resonance methods, the S_2 spectrum would be impenetrably complex. Further, the excited state of interest and the ground state of S_2 both have *gerade* parity. Recalling the selection rules listed in Table 1, we see that the excited state can only be reached by a spectroscopy that involves use of an even number of photons. The final state in this case is an ion pair state of S_2 , a state that is best described as a pair of oppositely charged ions, S^+S^- , rather than a covalently bound $S=S$. As for Rydberg states, most if not all molecular species will have such ion pair states but, to date, their observation remains quite rare. This is because the equilibrium bond length in an ion pair state is generally much larger than in the ground state, with the result that the two states show little Franck–Condon overlap. Double-resonance spectroscopy can provide a means of accessing such states if, as here, and as illustrated, the first step is to the inner turning point of the wavefunction associated with a high vibrational level of an intermediate valence excited state while the second step is arranged to excite from near the outer turning point of this same vibrational level to the ion pair state of interest. In the case of S_2 , the ground and ion pair states have B rotational constants of 0.30 cm^{-1} and $\sim 0.13\text{ cm}^{-1}$, respectively, implying a 50% extension in equilibrium bond length when undergoing this

double-resonant excitation. The versatility illustrated by these few examples serves to explain why multiphoton excitation methods in general, and REMPI in particular, continue to find widespread use as one of the most general and most sensitive species-selective methods of detecting atoms and small molecules (including radicals) in the gas phase.

REMPI–Photoelectron Spectroscopy (PES)

We now consider the photoelectrons formed in the MPI process, and the information they may carry. The measurement of their kinetic energies has become an established technique, thereby providing a means of performing photoelectron spectroscopy on excited electronic states. Such measurements can therefore give important clues as to the electronic and vibrational make-up of the excited state. They also allow determination of such details as the number of photons involved in the overall ionization process and the source of any fragment ions. For example, a given daughter ion, Y^+ , seen in the TOF spectrum of the ions resulting from REMPI of a parent, XY , can arise from photodissociation of the neutral parent followed by one- (or more) photon ionization of the fragment, i.e.

or from MPI followed by photodissociation of the resulting parent ion, i.e.

or as a result of direct dissociative ionization of the parent, i.e.

Given the pulsed nature of the REMPI process, the electron KEs are almost always measured by TOF methods, either using a conventional (mu-metal-shielded) TOF spectrometer or a magnetic bottle photoelectron spectrometer. The latter offers the advantage of much higher collection efficiency, with comparatively little loss of ultimate KE resolution.

Recalling **Figure 1b** we note that when an MPI process is resonance enhanced by a bound excited state B, the vibrational structure in the resulting photoelectron spectrum will reflect the differences in the equilibrium geometries of state B and the parent ion, rather than between the ground state A and the ion as in traditional one-photon (e.g. He I) PES. Thus if the geometry and the vibrational level structure of the ion are already known, the vibronic structure evident in REMPI-PES can yield insight into the geometry of the resonance enhancing state B. If B is a pure Rydberg state, the electronic configuration of its core should be the same as that of the ionic state that lies at the convergence limit of the series to which it belongs. The Rydberg state and the ion will therefore be likely to have very similar geometries. Thus, by the Franck–Condon principle, we can anticipate that the final ionizing step in a REMPI process via such a Rydberg state will involve a $\Delta v = 0$ transition, leading to selective formation of ions with the same vibrational quantum number(s) as in state B. Since the photoionization is brought about using a (known) integer number of photons, the photoelectrons accompanying such state specific ion formation will have a narrow spread of KEs. In favourable cases the TOF spectrum of these photoelectrons can be resolved to the extent that individual rotational states of the ion are revealed, thus explaining the continuing appeal of REMPI-PES as a means of determining accurate ionization thresholds and of investigating photoionization dynamics in simple molecular systems.

Another form of PES has emerged that can provide a further order of magnitude improvement in energy resolution (i.e. cm^{-1} resolution). This technique is now generally referred to as zero kinetic energy (ZEKE)-PES. In conventional photoelectron spectroscopy, and in

REMPI-PES, we learn about the energy levels of the ion by measuring the photoelectron KEs as accurately as possible. ZEKE-PES also reveals the energy levels of the cation but is based on a different philosophy. The principle of the method is illustrated in **Figure 5**. In the particular double-resonant variant shown, one laser is tuned so as to populate a (known) excited state M, and a second laser pulse is then used to excite this population to the energetic threshold for forming one of the allowed quantum states of the ion. Any energetic electrons (e.g. those formed via an autoionization process) will quickly recoil from the interaction region. The ZEKE (threshold) electrons can be detected by application of a suitably delayed pulsed extraction field. A ZEKE-PES spectrum is obtained by measuring the excitation spectrum for forming photoelectrons with zero kinetic energy; precise energy eigenvalues are obtained because the spectral resolution is determined, ultimately, by the bandwidth of the exciting laser. It is now recognized that this description, while appealing, actually oversimplifies the physics. The ‘ZEKE’ electrons detected in an experiment as described actually derive from pulsed-field ionization of very high Rydberg states belonging to series converging to the threshold of interest. As a result, the ionization thresholds determined via this type of experiment will all be subject to a small, systematic shift to low energy. However, the magnitude of this shift scales with the applied extraction voltage, so the true thresholds can be recovered by recording such spectra using a number of different pulsed extraction voltages and extrapolating the observed line frequencies to zero applied field.

Figure 5 Illustration of two-colour two-photon ZEKE excitation scheme, in which the first photon is fixed so as to be resonant with a known $M \leftarrow A$ transition and the frequency of the second photon is tuned. As shown in the inset, the peaks in a ZEKE spectrum correspond to the onsets of new ionization thresholds.

Ion Imaging

As REMPI is a very sensitive, selective and convenient means of detecting small localized concentrations of gas phase species, it is particularly suited to probing atomic or molecular products resulting from a gas-phase photodissociation or a crossed-beam reaction. Accurate knowledge of the energy disposal in such products, their recoil velocities and the angular distribution of these velocity vectors, the alignment of their rotational angular momenta, and the way all these quantities are correlated, can provide considerable insight into the detailed dissociation and/or reaction dynamics. Ion imaging is one way in which REMPI spectroscopy is being used to provide such information. The experiment is simple in concept. In the case of photodissociation, the precursor of interest, in a skimmed molecular beam, is photolysed to yield fragments, one of which is ionized selectively and in a quantum state-specific manner, by REMPI, as soon as it is created. The resulting cloud of ionized fragments continues to expand with a velocity and angular distribution characteristic of the original photolysis event, but is simultaneously accelerated out of the interaction region and arranged to impact on a position-sensitive detector, e.g. a microchannel plate behind which is mounted a phosphor screen that is viewed using a gated image-intensified CCD camera. The result is a squashed two-dimensional projection of its initial 3D recoil velocity distribution. This can be reconstructed mathematically to yield the speed and angular distributions of the tagged fragment, in the particular quantum state defined by the REMPI excitation wavelength. The structure in the image provides information about the speed and angular

distribution of the tagged fragments and also, by energy and momentum conservation arguments, the quantum state population distribution in the partner fragments; such knowledge can provide a uniquely detailed view of the parent photofragmentation dynamics. By way of illustration, **Figure 6** shows ion images obtained by ionizing ground-state ($^2P_{3/2}$) Br atoms resulting from photolysis of Br_2 molecules at three different wavelengths. It is clear from these that the velocity and angular distribution of these Br atoms (defined relative to the electric vector, ϵ , of the photolysis laser – vertical in **Figure 6** as indicated by the double-headed arrow) depends on the photolysis laser wavelength. The radii of the partial rings apparent in each image give the speed of the atoms and hence, by energy conservation, the energy of the other fragment. The middle image reveals that Br_2 photolysis at 460 nm yields ground-state $\text{Br}(^2P_{3/2})$ atoms (the tagged species) in conjunction with both another ground-state atom (outer ring) and a spin-orbit excited-state ($^2P_{1/2}$) partner, the inner ring. These product sets show different recoil anisotropies. The relative intensities of the two partial rings provide a measure of the branching ratios into these two product channels. Clearly, dissociation via a perpendicular transition (v_{recoil} perpendicular to ϵ) yielding two ground-state Br atoms is the dominant decay mechanism at 400 nm, whereas at longer excitation wavelength (e.g. 480 nm) the dominant fragmentation is to one ground-state ($^2P_{3/2}$) and one spin-orbit excited-state ($^2P_{1/2}$) Br atom, following a parallel excitation process. Analysis of images like these, and their dependence on photolysis wavelength, can provide much insight into both the mechanism and the timescale of the dissociation process.

Figure 6 Ion images of ground-state Br ($^2P_{3/2}$) atoms resulting from Br_2 photolysis at the specified wavelengths. The double-headed arrow indicates the plane of polarization of the photolysis laser radiation.

Introduction, Basic Ideas, Terminology

Spectroscopic methods are increasingly becoming the methods of choice for analysing a variety of experimental data, in chemistry, biology, food industry, medicine, etc. This popularity is well deserved. The spectral methods are generally faster, more accurate and frequently much cheaper than conventional analytical techniques. Furthermore, in biomedical applications they provide the means for noninvasive or minimally invasive diagnosis. However, these obvious advantages are somewhat offset by the indirect relationship between spectral features and the measurables or observables of interest (such as analyte concentrations or disease class assignments).

Consequently, we have to model a generally complex and frequently nonlinear relationship. This relationship can be represented by

$$Y = F(X) \quad [1]$$

where $Y = \{y_1, y_2, y_3, \dots, y_K\}$ is the set of K measurables (responses, observables, targets) (e.g. the concentrations of K analytes or membership labels for K classes), $X = \{x_1, x_2, x_3, \dots, x_N\}$ is the collection of N samples (objects, patterns), with x_k the k th sample. Every sample is represented as an L -vector, with each of its L elements corresponding to one of the L spectral features (attributes, predictor variables, measurements) (such as wavelengths or frequencies), i.e. $x_k = \{x_k(1), x_k(2), x_k(L)\}$, and F is the model (function) that couples Y with X and whose parameters we are to optimize, implicitly or explicitly. Any practical scheme of optimization must necessarily be data-driven. Hence the larger the N , the number of samples, the more reliable any prediction based on eqn [1]. In spectroscopy (whether infrared, IR, magnetic resonance, MR, or other), K (the number of analytes or the number of classes) typically ranges from one to about a dozen, L (the number of spectral wave-numbers or frequencies) is in the hundreds or thousands, and N ought to be at least in the hundreds. Since in spectroscopic applications L , the dimension of the feature space, is invariably greater than one, and typically large, multivariate methods of analysis are necessary. Furthermore, L is frequently larger than N , the sample space dimension. As this causes numerical problems, special approaches are needed and precautions have to be taken. These we can handle via some preprocessing procedure. Its most important goal is data reduction (compression). In practice, data compression is divided, somewhat artificially, into feature extraction or feature subset selection.

Exploratory data analysis and representation is usually the first step in probing the functional relationship between Y and X . This falls into the purview of unsupervised pattern recognition, with clustering methods the most common representatives. Hierarchical clustering is the oldest, having its roots and initial applications in taxonomy, psychology and the social sciences. Its limitations are due, paradoxically, to its flexibility: by changing the merging (or splitting) criterion and/or the dissimilarity measure, we can create almost any grouping of the samples. The final number of clusters depends on a user-selected threshold; hence it is subjective. The fact

that the samples are partitioned into mutually exclusive (non-overlapping) groups must be regarded as unrealistic.

The other major variant of clustering minimizes some objective function of the intersample distances. The results are also dependent on user-selected parameters (e.g. the number of clusters and the type of the distance measure used). However, these results become more realistic if we allow overlap between clusters, i.e. if we accept that the samples can be fuzzy, having memberships in all clusters. Bezdek's fuzzy c -means clustering algorithm is the most popular of such clustering methods. Neither clustering variant can be expected to outperform methods based on supervised pattern recognition.

Although calibrating or classifying spectra are merely two different applications of the mathematical/statistical technique of regression, historically they have evolved independently, with different goals and requirements. Whenever possible attempts will be made to connect the two by drawing attention to common concepts and methods that only differ in their terminology and emphasis. Occasionally, for the sake of simplicity in presentation, discussion will cover certain aspects and peculiarities of the two disciplines separately.

Calibration *is* regression, but with a specific connotation: it involves the development of a quantitative, and generally linear relationship between, say, the concentrations of the analytes present and their spectral manifestations. Significantly, this relationship is continuous. In contrast, classification assigns class labels to the samples and thus establishes a categorical correspondence between the samples and their spectral features, a generally discrete relationship.

Both calibration and classification belong to the group of supervised pattern recognition methods. Supervision means that the model parameters in eqn [1] must be optimized using information provided by and extracted from the available data. To do this so that prediction is reliable and robust, leads naturally to the concept of partitioning the samples into training (design, learning) and validation (test, prediction) sets.

This article will focus on concepts and ideas, without delving into detailed description of individual methods. The interested reader is directed to Further Reading for more in-depth accounts and discussions.

Preprocessing

The characteristics of spectra demand that we use preprocessing to guarantee that the predictions from the optimized eqn [1] are reliable and robust. In fact, extensive experience suggests that if the preprocessing part of the analysis is done properly, then even the simplest calibration or classification methods will succeed.

At its most straightforward, eqn [1] describes some simple functional transformation of the original data. This might be as elementary as mean-centring and scaling ('whitening'), i.e. subtracting the overall sample mean from each individual sample and dividing by the sample variance. Other useful examples include smoothing (filtering), normalization (e.g. by the overall area under the spectra), monotonic nonlinear operations (e.g. using the logarithms or powers of the spectral intensities), and analysing the (numerical) derivatives of the original spectra. For instance, the assignment of mid-IR spectra of biofluids into different disease classes is most successful when the classifier uses the first derivatives of the spectra.

Extracting some intrinsic structure from the data, while in the original L -dimensional feature space, is rarely successful because the majority of the L spectral features are either redundant (typically owing to correlation) or represent irrelevant information ('noise'). Any of these will usually mask the discriminating features. We then interpret preprocessing as either a procedure that removes irrelevant features (a type of filtering) or one that finds the optimal subspace in which the data can be best analysed (a form of projection).

The number of spectral features L is generally large and frequently larger than N , the number of samples. Furthermore, (adjacent) spectral features are often strongly correlated, i.e. they are not independent. If $L > N$, linear dependency or near-dependency (called multicollinearity by the calibration community) could lead to numerical instabilities, with consequent unreliable and non-reproducible results. For instance, when classifying spectra via linear or quadratic discriminant analysis (LDA or QDA), the occurrence of singular or near-singular covariance matrices causes matrix inversion problems. The overall conclusion, supported by extensive experience, is that we must somehow reduce the number of features. Although no general theoretical proof is available, in practice the ratio $N:L$ should be at least 10, but preferably 20, for reliable classification or calibration results. Instead, for spectra this ratio is more likely to be 0.1 or even less.

Data reduction can be achieved by feature extraction, which first transforms the original L variables $\mathbf{X}$ into L new variables $\mathbf{Z} = \mathbf{G}(\mathbf{X})$. $\mathbf{G}$ is nonlinear in general. However, principal component analysis (PCA), the most commonly used transformation, is linear: $\mathbf{Z} = \mathbf{A}\mathbf{X}$, where $\mathbf{A}$ is a matrix. PCA is an unsupervised method, applied to the entire available data. It is carried out by diagonalizing the sample covariance matrix $\mathbf{S}$. If we sort the resulting eigenvalues in decreasing order, then the corresponding eigenvectors (principal components, PCs) point, in the original L -dimensional feature space, in directions of successively decreasing variance. The PCs are orthogonal and uncorrelated. Geometrically, PCA corresponds to a

rotation of the original L coordinate axes to L new orthogonal axes formed by the L PCs. We achieve the data reduction by retaining only the first $M \ll L$ PCs (Z s) for further analysis. (Recall that the PCs are different linear combinations of all L original features.) However, the first M PCs, even if they account for a large fraction of the total variance in the data, are not necessarily the most discriminating directions along which classes may be separated. In fact, it is more useful to select those M PCs that give rise to the lowest classification error. These are generally not the first M in the ordered list. Similarly, in calibration, it makes more sense to select those M PCs that show maximum correlation with the Y . Such arguments lead naturally to the other data reduction method, feature subset selection. As a first application, we could select from the L PCs the M that best satisfy the above requirements. This is always beneficial. However, the general approach has several attractive characteristics which don't depend on a prior PCA, especially for features originating in spectra. The foremost of these is that the features of the optimal subset retain their spectral identity. This is, of course, important for interpretability, especially in MR spectroscopy, where the spectral peaks are relatively narrow and have distinct chemical identities. Another significant practical advantage is that once we identify a smaller subset of the complete set of features we never need to determine or measure the remaining features again.

Assume that we wish to select the $M \ll L$ best features, with 'best' defined appropriately for the given application. The naive approach of combining the individually best M features rarely produces the best M -feature subset. Examining all possible M -feature subsets to find the best is usually prohibitive computationally. A possible solution is to restrict the search to a subspace of the complete space of all feature sets. The standard stepwise methods proceed along these lines. The forward selection (FS) version is computationally the least demanding. FS starts by selecting the M individually best features. This is repeated, at each stage adding that feature which, when combined with those already chosen, gives the best result. The backward elimination (BE) algorithm starts with the complete set of features and sequentially removes the one that least degrades performance. The BE method is computationally prohibitive when the starting set of features is large, as is the case for spectra. Both have been generalized (e.g. more than one feature can be added or removed at a time). FS and BE can also be combined. Neither method is guaranteed to find the globally optimal M -feature subset. Branch-and-bound methods, which would guarantee the best possible subset, are rarely applicable to spectra. More recently, optimal feature selection techniques based on genetic algorithms (OFS-GA) have been used with great success. The approach is natural for

preprocessing spectra or time series, for which the feature set originates from sequential discrete sampling from or measurement of an underlying continuum. Consequently, the dimensionality L of the original feature space is large. The inherent order (along time or wavelength) implies that adjacent features will be correlated, a characteristic that causes redundancy. Unlike BE, OFS-GA can start with the original feature space. It maps this onto a bit string (zeroes and ones). GA operations, such as mutation and crossover, are used on a population of bit strings. The performance criterion is the minimization of an objective (fitness) function F . If F is the mean square error between the training set classification results and the a priori class indicator, then the best F simultaneously maximizes the overall accuracy for the training set and the crispness of the class assignments. The input to the algorithm is M , the ultimate number of features (distinct subregions) required, and the type of feature space-reducing operation or transformation to be carried out in these subregions. Typical operations include (but are not confined to) replacing the individual features in a subregion by their average or variance. Selecting an $M \ll L$ and one of these operations leads jointly to substantial feature space reduction.

Training versus Test Sets and Crossvalidation

Suppose we knew exactly the multivariate distributions from which we drew our samples. Then, at least in principle, we could calculate the true error (called the Bayes error, e_B , which is the smallest achievable error given the exact distributions). In practice, we have a finite, limited number of N samples. When the samples are random and N is sufficiently large to be representative of the underlying distributions, the entire data set can be used to optimize the calibration or classifier parameters. Then predicting the concentrations of the K analytes present in a new sample (calibration), or assigning this sample to one of the K classes (classification), is analogous to interpolation. In contrast, for the typical case of small or moderate N , prediction or class assignment corresponds to the much less reliable process of extrapolation. Thus, in most practical situations two contradictory requirements confront us. On the one hand, for reliability we would like to use all N samples. When this is done, it is called the resubstitution (plug-in) method in the classification literature. However, the resubstitution or apparent error estimate e_R is generally overoptimistic. The danger of overfitting threatens, without any guarantee that new samples, not used for training, would be correctly predicted or assigned. The consequence of overfitting is that the classifier or regressor will have poor generalizing power. On the other hand, let us partition

the N available samples into independent training and validation sets, with N_T and N_V ($N = N_T + N_V$) samples, respectively. Then we may satisfy validation requirements, but reliability suffers because N_T is not sufficiently large.

Crossvalidation techniques may be used to compensate for the smallness of the sample set (unfortunately far too frequent in biomedical applications). Lachenbruch proposed the leave-one-out or delete-1 ($D_{[1]}$) method (a close relative of Tukey's jackknife). For classification problems this proceeds by successively deleting each of the N samples from the data set, training a classifier on the remaining $N-1$, and assigning the deleted sample to one of the classes ($N_T = N-1$ and $N_V = 1$). Thus we create and test $N(N-1)$ -sample classifiers, each with performance only very slightly worse than that of the complete N -sample classifier. (The entire process is identical for calibration, with 'classification' and 'classifier' replaced by 'regression/calibration' and 'regressor'.) The result is a much-reduced bias for the classification (calibration) error, $e_{D[1]}$. Unfortunately, for small or even moderate N the variance can be large. The delete- d ($D_{[d]}$) crossvalidation strategy can reduce the variance. The complete delete- d ($CD_{[d]}$) version produces $N!/d!(N-d)!$ classifiers, a huge number even for moderate N . (If $N = 50$ and $d = 10$, this number is $\sim 1 \times 10^{10}$.) Thus, in practice we select uniformly a random subset of size B out of these. As long as $N/B \rightarrow 0$, e.g. with $B = N^\delta$, $\delta > 1$, the $D_{[d]}$ strategy retains the efficiency of the $CD_{[d]}$. The expected classification error is the average of the B individual errors, as measured on the B sets of d deleted, i.e. test samples.

The above are examples of nonparametric resampling (RS) methods, without replacement. The deservedly popular bootstrap method is also a resampling method, but with replacement. Because of replacement, some objects may appear several times in any of the B bootstrap samples. This could cause difficulties for those classifiers that we optimize by inverting covariance matrices. A simple remedy is to perform the sample replacement only after we have selected for the current training set a particular subset of $N-d$ distinct samples. Again, we secure the end result by averaging the B individual classifier outcomes.

Resampling, based on a random (Monte Carlo) subset selection is a very powerful crossvalidation approach. It is not constrained by the computational limitations of the $CD_{[d]}$, even for $d \approx N/2$. Furthermore, such resampling methods are equally effective in providing nonparametric confidence intervals/regions for any computed estimate.

(Supervised) Classification Methods

These fall into two categories: parametric and nonparametric. The former assumes that the samples for the K

classes derive from some known distribution (usually multivariate normal), whereas the latter is distribution-free. There is no best method: the choice of the classifier depends both on the problem and on the property that we want to optimize. Most frequently, we minimize the classification error, in particular e_V for the validation set, but this need not be the only choice. Our current concern is with the classification of spectra. In the following, we shall assume that the original, L -dimensional feature space was already reduced to an M -dimensional space, $M \ll L$ (M -space).

Fisher's LDA method is still the workhorse of the parametric methods. Of all the statistical classifiers, we understand LDA's theoretical properties best. We can derive it from ordinary (linear) least-squares (OLS) regression. LDA creates those linear combinations of the M features that best separate the classes. For each class k there is one of these discriminant functions d_k . The decision surfaces $g_{jk} = d_j - d_k = 0$ between any pair (j, k) of classes are also linear, i.e. they are hyperplanes in M -space. The properties of LDA are optimal in the Bayes sense if all K distributions are multivariate normal and have a common covariance matrix S . In practice, these conditions are rarely satisfied. Nevertheless, LDA is surprisingly robust against even moderate deviations from normality and/or from the equality of the covariance matrices. LDA requires the optimization of $M+1$ parameters for an M -dimensional feature space, the minimum number for a parametric statistical classifier.

If the covariance matrices S_k are different, then the classifier created is called quadratic discriminant analysis (QDA). The hypersurfaces separating the classes become quadratic (curved). Unfortunately, this additional flexibility comes at a cost: we have to optimize $O(M^2)$ parameters instead of the $O(M)$ in LDA. Usually $O(M^2) \gtrsim N$, leading to overfitting, numerical instabilities, etc. Furthermore, QDA is less reliable, because it uses the $K S_k$ s, each an estimate of the (generally unknown) population covariance matrix, whereas LDA uses the more reliable single, pooled sample covariance matrix.

Friedman suggested regularized discriminant analysis (RDA) to alleviate some of these problems. RDA introduces a two-parameter estimate of the sample covariance matrix. If S_k is the sample covariance matrix for class k , and S their pooled version, then we construct a two-parameter covariance matrix $S_k(\lambda, \gamma)$, $0 \leq \lambda \leq 1$, $0 \leq \gamma \leq 1$. The four corners defining the extremes of the λ, γ parameters represent well-known classifiers; ($\lambda = 0$, $\gamma = 0$) corresponds to QDA, ($\lambda = 1$, $\gamma = 1$) to LDA, whereas ($\lambda = 1$, $\gamma = 1$) gives the nearest-means classifier (assigning a sample to the class with the nearest training set mean, using Euclidean distance). When ($\lambda = 0$, $\gamma = 1$) a variance-weighted version of the nearest-means classifier is generated. The optimum (λ, γ) pair is usually determined via crossvalidation. Excellent results have been reported

even when the 'number of samples' to 'number of features' ratio $N:M$ was unfavourably low.

RDA modifies (shrinks) the eigenvalues of the original covariance matrices. Other methods exist with similar goals. Amongst these is DASCO (discriminant analysis with shrunken covariances). Although popular with the chemometric community, DASCO is quite complex, yet does not outperform RDA or the simpler ridge method. The latter also modifies the sample covariance matrix to be used with LDA from $\mathbf{S}$ to $\mathbf{S} + \alpha \mathbf{I}$, where α is a parameter to be optimized, and $\mathbf{I}$ is the unit matrix.

Among the nonlinear methods, neural net (NN) classifiers are more recent. Conceptually attractive, they are frequently used uncritically. A common danger is overfitting: because of the essentially unlimited flexibility of multilayer NNs, the training set can be classified perfectly (by creating an arbitrarily convoluted and complicated decision surface). Unfortunately, this high classification accuracy does not generally carry over to the validation set.

Recursive partitioning (decision tree) methods had found early use in numerical taxonomy, the social sciences and medicine. More recently, researchers in both artificial intelligence and statistics have substantially advanced these methods. There are two major types. Binary decision trees would be relevant in medical diagnosis, where the features are symptoms, with only yes/no answers for the decisions. If the features are continuous (spectral features qualify) then the decision trees are more complex, requiring the partitioning of each feature. The partitioning criteria and the sequence in which the features are probed are aspects of the tree design. The major advantage of the decision tree methods is ease of interpretability. To apply these methods to spectra, prior feature space reduction seems mandatory.

The nearest neighbour (nn) methods are nonlinear, nonparametric classification methods. They estimate probabilities at x using the classes of adjacent training set points. The estimates will have smaller bias if only close neighbours are used, hence nearest neighbours. In applying these methods a distance measure, e.g. Euclidean, is needed. Among the advantages are simplicity and an upper bound on their asymptotic misclassification error: $e_{nn} \leq 2e_B$. A major disadvantage in a high-dimensional feature space is the unacceptably large number of training samples required for accuracy.

Calibration Techniques

A major desideratum in most calibration work is linearity. If the relation between $\mathbf{Y}$ and $\mathbf{X}$ (eqn [1]) appears nonlinear, then either the $\mathbf{X}$ or the $\mathbf{Y}$ (or both) is transformed until linearity is achieved. This is important for accurate, quantitative predictions of continuous responses such as

analyte concentrations. This preoccupation with linearity guided the development of the most important calibration methods.

Because of their common origin (i.e. regression), calibration methods share many characteristics with classification methods. Nevertheless, we can introduce most calibration techniques more simply in terms of their original formulation. Furthermore, several of these methods treat data reduction and calibration (fitting) simultaneously. Wold's partial least squares (PLS) regression reduces the number of features on which the OLS regression is carried out. This is done by feature extraction, i.e. from the raw features the algorithm produces 'derived features' (DFs, the partial least squares). The first DF is the linear combination of the L original features that has maximum covariance (rather than correlation) with $\mathbf{Y}$. Subsequent DFs are found in the same way, subject to being uncorrelated with previous ones. PLS can be described in terms of covariance regularization (maximization).

Principal component regression (PCR) is intimately related to PCA. If the spectral decomposition (diagonalization) of the cross-product matrix $\mathbf{X}'\mathbf{X}$ is

$$\mathbf{S} = \sum_{k=1}^L E_k \mathbf{u}_k \mathbf{u}_k'$$

then in PCR the matrix

$$\mathbf{S}^{-1} = \sum_{k=1}^M E_k^{-1} \mathbf{u}_k \mathbf{u}_k'$$

is used, where $M \ll L$. $\mathbf{u}_k$ is the k th PC and the M PCs are usually chosen to have the highest correlation with $\mathbf{Y}$. There are other methods, e.g. shortest least squares, but the above two are used most frequently.

Discussion

Is there a best method for classification or regression? The answer must be: 'It depends on the data and the criterion to be optimized'. Nevertheless, some general recommendations can be made. The first is that pre-processing the data is probably the most important step to be taken for reliable, reproducible results. The second is that crossvalidation is essential if we want reliable predictions for new samples. Finally, as many samples should be collected as possible. If at least the first two are carried out properly, then even the simplest classifiers or regressors will work well. However, the most important message is: know your data!

Some important topics could not be dealt with because of space limitation. Outlier detection is amongst these. Every attempt should be made to find outliers

before classification or calibration is carried out, otherwise the results will be distorted.

A_k	nuclear hyperfine coupling constant
A_μ	muon hyperfine coupling constant
A'_μ	reduced muon hyperfine coupling constant
$\tilde{A}_\mu$	muon hyperfine coupling tensor
$A_\parallel$	decay asymmetry
B	magnetic field strength
B_{ij}	anisotropic components of the hyperfine coupling
e^+	positron
E_a	activation energy for reaction
k	reaction rate constant
k_{ch}	chemical reaction rate constant
k_{ex}	spin-exchange reaction rate constant
M	spin quantum number
N_b	'backward' decay positron count
N_f	'forward' decay positron count
T_c	critical temperature for phase change
T_m	melting point
ΔM	change in spin quantum number
ΔH_R^0	reaction enthalpy
γ_μ	muon gyromagnetic ratio
κ	tunnelling transmission coefficient
λ	relaxation rate
μ^+	positive muon
μ_p	proton magnetic moment
μ_μ	muon magnetic moment
$\nu(e)$	electron neutrino
$\nu(\mu)$	muon neutrino
$\bar{\nu}(\mu)$	muon antineutrino
ν_μ	muon precession frequency
ν_{Mu}	muonium precession frequency
ν_R	radical precession frequency
τ_μ	muon lifetime

Spin-polarized positive muons, when injected into matter, can serve as magnetic probes for the investigation of various properties. The evolution of muon spin polarization rests on the same basis as conventional magnetic resonance techniques, but the methods involved in exploiting these probes are considerably different. The basic elements of muon spin resonance spectroscopy are

described, with an emphasis on spectroscopic and kinetic applications in chemistry.

The Positive Muon, a Magnetic Probe

Muon spin resonance spectroscopy is an offshoot of the experiment that proved parity nonconservation in pion and muon decay. The observation that the initial amplitudes and the relaxation rates of the muon precession signals depended on the nature of the stopping medium led to a new analytical method that is closely related to Fourier transform magnetic resonance.

The positive muon μ^+ is an elementary particle that in the present context is best regarded as a light proton with a mass one-ninth that of the proton. Like the proton it is a spin- $\frac{1}{2}$ particle, but its magnetic moment is 3.18 times μ_p . It is available for experiments as spin-polarized beams that can be implanted into most environments and then used to probe the local magnetic field, either as static spectators or by sampling a certain region as a mobile species. Because of its low mass and low linear energy transfer during the thermalization process, the muon causes relatively little damage near its stopping site. Nevertheless, it can probe radiation-chemical effects near the end point of its thermalization track.

In some environments the positive muon can capture an electron to form a hydrogen-like atom with the μ^+ as a nucleus. Called muonium (Mu), this atom behaves chemically as a light hydrogen isotope. It is a paramagnetic species that can also serve as a static or diffusing magnetic probe. Some of the properties of muons and muonium are summarized in **Table 1**. Chemical reaction of Mu with unsaturated molecules leaves the muon as a polarized spin label in organic free radicals, for example

Such species are routinely observed and can be characterized spectroscopically.

In comparisons of muons with protons and of muonium with hydrogen atoms, pronounced quantum effects occur whenever dynamics are involved. In this way, muons have been utilized to probe a large variety of properties and materials: insulators, semiconductors,

Table 1 Properties of μ^+ and Mu

	Property	Symbol	Value ^{a,b}
μ^+	Mass	m_μ	$1.883\,53 \times 10^{-28}$ kg = 0.1126 $m_p = 206.7864\,m_e$
	Lifetime	τ_μ	2.197 134 μ s
	Spin	I	$\frac{1}{2}$
	Magnetic moment	μ_μ	3.183 344 μ_p
	Gyro-magnetic ratio	γ_μ	135.54 MHz T ⁻¹
Mu	Mass	m_{Mu}	0.0113 15 m_H
	Bohr radius	a_0 (Mu)	0.053 17 nm = 1.0043 a_0 (H)
	Ionization potential	I (Mu)	13.539 eV = 0.9957 I (H)

^a μ_p = magnetic moment of the proton.

^bH = hydrogen.

metals, superconductors, insulators, gases, liquids, crystalline and amorphous solids, static and dynamic magnetic properties of all kinds, electron mobility, quantum diffusion, chemical reactivity and molecular structure and dynamics. The term adopted for the broad field of muon spin spectroscopy techniques, μ SR, emphasizes the analogy with other types of magnetic resonance; for example EPR. ‘ μ S’ represents ‘muon spin’, and ‘R’ in a more general sense stands simultaneously for ‘rotation’, ‘relaxation’ and ‘resonance’.

Muon Production

Muons are produced artificially from pions (pi-mesons) formed by the collision of energetic protons with low- Z targets. The pions decay with a lifetime of 26 ns:

$$\pi^+ \rightarrow \mu^+ + \nu(\mu) \quad [2]$$

The neutrino, ν , has negative helicity (angular momentum antiparallel to linear momentum), so from conservation laws the muon must also have negative helicity. By momentum selection, muon beams are obtained with a polarization close to 100%.

Two types of positive muon beams are possible: (1) surface muons, arising from pions decaying at rest close to the surface of the production target, with a momentum of 28 MeV/ c and a stopping range of 140 mg cm⁻² (corresponding to a water layer 1.4 mm thick); and (2) decay muons, from pions decaying in flight, having a selectable momentum normally in the range 70–130 MeV/ c , and requiring a stopping range up to several centimetres of water. Surface muons are often preferred since they allow the use of thinner samples. They are also amenable to in-flight spin rotation where the crossed electric and magnetic fields of a Wien filter can be used to orientate their polarization with respect to their momentum.

Muon beams can be further classified on the basis of their time structure. Quasi-continuous muon sources allow high-precision measurement of the time interval between the arrival of the muon and its decay. However, the requirement in most experiments that each muon decay before the next is admitted to the sample limits the usable flux to about 10⁵ muons per second. Pulsed beams avoid this pile-up limit since a large number of muons are stopped simultaneously, followed by a long delay during which the decay of most muons can be accumulated, leading in principle to background-free histograms and a longer time window. Pulsed beams are also ideally suited for experiments that require coincidence with other pulses, e.g. laser or radiofrequency excitation.

Detection of Muon Polarization

Conventional magnetic resonance uses radiofrequency techniques to detect the time evolution of spin polarization. This is impossible in muon spin resonance because of the extremely dilute concentration of the probes within the sample (often no more than one muon at a time). However, the decay of the muon

$$\mu^+ \rightarrow e^+ + \nu(e) + \bar{\nu}(\mu) \quad (\tau_\mu = 2.197 \mu\text{s}) \quad [3]$$

does not conserve parity, leading to an anisotropic decay in which the positron (e^+) is emitted preferentially along the instantaneous direction of the muon spin at the moment of decay. Detection of the decay positron (and also of the muon’s arrival in the case of time-differential experiments at a continuous-beam facility) involves standard particle-physics techniques, typically scintillating detectors coupled to photomultiplier tubes. Collection of an ensemble of correlated muon–positron events as a function of time and/or magnetic field in a given direction from the sample allows the evolution of muon polarization to be monitored.

Thus the basic methods of muon spin resonance differ considerably from those of conventional magnetic resonance spectroscopy. First, the probe is delivered to the sample with its spin polarization already prepared, and second the evolution of the polarization is monitored statistically by collecting information on the decays of individual probes.

Experimental Techniques of Muon Spin Resonance

Transverse-Field Muon Spin Rotation

The transverse-field μ SR (TF- μ SR) technique is shown schematically in **Figure 1a**. Muons enter the sample S either perpendicular to the magnetic field (as shown in **Figure 1a**) or (for a spin-rotated surface beam) along the field axis such that their polarization is perpendicular to

Figure 1 Schematic drawing of the experimental apparatus used for muon spin resonance spectroscopy: (a) time-resolved transverse-, longitudinal- and zero-field studies; (b) time-integrated longitudinal fields (ALC).

the field. Each arrival is detected by a muon counter that starts a clock to measure the individual muon lifetime (at pulsed-beam facilities the start signal is synchronized to the muon pulse). The clock is recorded when the corresponding decay positron is detected in a positron counter, e.g. f or b, and the event is stored in a histogram $F(t)$ of decay positrons as a function of time spent by the muon in the sample. In the absence of any time evolution of the muon polarization, $F(t)$ is simply the radioactive decay curve (dashed line in **Figure 1a**) that corresponds to the muon decay. In a nonzero local magnetic field the muon will undergo a free induction decay (FID), similar to the response after a $\pi/2$ pulse in conventional magnetic resonance. Owing to the decay anisotropy (eqn [3]) the FID appears in the histogram superimposed on the muon decay curve. $F(t)$ takes the shape indicated schematically in **Figure 1a**.

In many cases, different muons find themselves in different magnetic environments in the same sample, resulting in an FID with multiple frequencies. In this case it is convenient to work with the Fourier transform (FT) of the time-domain data, just as for conventional magnetic resonance. This is sometimes called FT- μ SR.

Zeeman precession of the diamagnetic muon occurs at $\nu_\mu = \gamma_\mu B_i$ where the local magnetic field B_i can deviate

from the applied external field as a result of Knight shifts. Muonium, on the other hand, is observed mostly in low fields where two characteristic intra-triplet precession frequencies of the combined muon–electron systems occur. Below ~ 2 mT they become degenerate at $\nu_{\text{Mu}} = 13.94 \text{ MHz mT}^{-1} \times B$. The two transitions are indicated in the Breit–Rabi diagram for Mu in **Figure 2** (ν_{Mu} , solid arrows). Two further allowed transitions are of very high frequency and not normally observed (indicated by broken arrows). Muonated organic free radicals, however, are studied more easily in high fields where the muon transitions degenerate into two, independent of any other magnetic nuclei that may be present, corresponding to the first-order ENDOR frequencies,

$$\nu_{\text{R}\pm} = \left| \frac{1}{2} A_\mu \pm \nu_\mu \right| \quad [4]$$

These are indicated for Mu in **Figure 2**. The muon hyperfine coupling constant A_μ is obtained directly as the sum of the two observed frequencies (or the difference, in fields where $[\frac{1}{2} A_\mu - \nu_\mu]$ becomes negative). In general A_μ is in fact the component of a tensor $\hat{A}_\mu$ so its value depends on the orientation of the radical to the magnetic field B ; however, most experiments are carried out with

Figure 2 Breit-Rabi diagram for muonium with transverse-field transitions indicated by arrows. The zero-field splitting corresponds to the muon hyperfine coupling constant ($A_\mu = 4463$ MHz for Mu). In high fields, the four eigenstates become pure Zeeman states ($|1\rangle = |\alpha^\mu \alpha^e\rangle$, $|2\rangle = |\beta^\mu \alpha^e\rangle$, $|3\rangle = |\beta^\mu \beta^e\rangle$, $|4\rangle = |\alpha^\mu \beta^e\rangle$).

fluid samples where motion of the radical averages out the anisotropy, so just the isotropic value is observed.

Zero-Field and Longitudinal-Field Muon Spin Relaxation (ZF- μ SR and LF- μ SR)

These experiments are performed in time-differential mode using the same setup as TF- μ SR, except that the external field is absent or is applied parallel to the muon spin polarization in the beam (either by rotating the magnet or by removing spin rotation).

Avoided-Level-Crossing Resonance (ALC- μ SR)

A basically different type of μ SR takes advantage of the effect of avoided crossings of magnetic energy levels and is commonly performed in a time-integral mode as a function of longitudinal magnetic field (**Figure 1b**). Decay positrons are counted in the 'forward' (N_f) and in the 'backward' (N_b) direction with respect to the incoming muon beam. Of interest is the decay asymmetry

$$A_{||}(B) = \frac{N_f - N_b}{N_f + N_b} \quad [5]$$

In sufficiently high fields, the eigenstates of any spin system are pure Zeeman states, and muons that are aligned with the external field are in an eigenstate where there is no time evolution of spin polarization, and $A_{||}(B)$ is constant. Coupling of the muon to an unpaired electron, as in Mu or muonated radicals, leads to eigenstates that are mixtures of Zeeman states in low

fields. The prepared non-eigenstate oscillates between eigenstates, resulting in partial depolarization of the muon and a strong field dependence of the detected decay asymmetry at low fields. The same effect operates at those high fields where there is an avoided crossing of two levels and eigenstates are mixtures of two Zeeman states. As **Figure 1b** indicates, sharp resonances are observed at these fields.

The resonances are distinguished by the selection rules $|\Delta M| = 0, 1, 2$, where M is the quantum number for the z component of the total spin. They appear to first order at resonance fields

$$B_r = \left| \frac{A_\mu + (\Delta M - 1)A_k}{2[\gamma_\mu + (\Delta M - 1)\gamma_k]} \right| \quad [6]$$

Thus, if A_μ is known, the nuclear hyperfine couplings A_k are readily obtained, as are their relative signs, usually a difficult result in conventional magnetic resonance. The technique has been applied to semiconductors and to insulators, where dipolar and quadrupolar terms are determined in addition to the isotropic hyperfine couplings of eqn [6].

Radiofrequency Resonance Techniques (RF- μ SR)

RF- μ SR resembles conventional CW (continuous wave) magnetic resonance, as it relies on resonance between an exciting RF field and a transition between two magnetic energy levels. The technique is of advantage, for example, for studying radicals in dilute solutions where the phase coherence of muon precession is lost in transverse fields during the formation process. The experiment is carried out in a longitudinal external field with a transverse RF field B_1 . At high RF power a narrow double-quantum transition is observed in addition to the two power-broadened lines. The experiment can be conducted at constant field and variable RF frequency, or perhaps more conveniently at constant frequency and variable applied magnetic field as demonstrated nicely in a report on endohedral Mu and exohedral Mu adducts of fullerenes.

Applications of Muon Spin Resonance Spectroscopy

To illustrate some of the experimental techniques outlined above, a selection of experiments using muon spin resonance spectroscopy is described.

Spectroscopy of Muonium-Labelled Organic Free Radicals

The prototypical sample used in μ SR spectroscopy is benzene (see eqn [1]). A raw histogram of the TF- μ SR data obtained in a benzene sample at an applied field of 0.2 T is shown in **Figure 3a**. The precession signal at 27 MHz arising from muons that have thermalized in a diamagnetic environment is easily seen, as is the overall decay curve due to the finite muon lifetime. **Figure 3b** shows the Fourier transform of the histogram, revealing not only the muon precession but also the ENDOR-like precession signals from muons which have reacted to form the free radical $\text{C}_6\text{H}_6\text{Mu}$.

Benzene is a simple example, since all addition sites are equivalent. However, consider 6,6-dimethylfulvene

(**Figure 4**). Here there are four possible addition sites and thus potentially four radicals can be formed. **Figure 5a** shows the FT- μ SR signal obtained in this compound at 0.3 T in ether solution. Two pairs of radical signals are seen, with hyperfine coupling constants of 105.2 and 203.5 MHz, respectively. To elucidate which radicals were observed, ALC spectra were also obtained for this compound (**Figure 5b**, lower trace). The resonances indicate where the muon's energy level has become degenerate with that of one of the H atoms in the radical (i.e. $\Delta M = 0$). Since the A_μ values are known from the FT- μ SR, it is possible to devise a simulation to model the ALC spectrum, obtaining the various A_p values within the radicals, and to assign these values to specific sites. The results indicate that the two radicals are those formed by addition at the 1 and 2 positions in the ratio

Figure 3 TF- μ SR spectra for positive muons implanted into benzene: (a) the raw time-differential histogram recorded for the experiment; (b) the Fourier transform of (a) showing the two transitions due to the $\text{C}_6\text{H}_6\text{Mu}$ radical (218.18 and 295.85 MHz, giving a hyperfine coupling constant of A_μ of 514.03 MHz) and the signal from muons in diamagnetic environments (27.1 MHz).

Figure 4 The structure of 6,6-dimethylfulvene (a) and the four radicals (b–e) that may be derived from it by Mu addition. 1.4:1. The derived coupling constants and spin populations for these radicals are given in **Figure 6**.

Note that the ratio of the reduced muon coupling A_μ' ($A_\mu' = A_\mu (\mu_p/\mu_\mu)$) to the proton coupling at the same site is somewhat higher than unity. This is typical for muonated organic free radicals, the isotope effect normally lying between +5% and +15%. This can be understood as a simple consequence of the larger zero-point vibrational amplitude of the lighter isotope. Since the potential well for vibration is anharmonic, the average bond length is also larger. In other words, the muon and electron are moved towards the configuration of a free Mu atom, where A_μ is much higher than in the radical, and so their hyperfine coupling constant is correspondingly increased.

As noted earlier, the hyperfine coupling constant A_μ is in fact the component of a tensor $\hat{A}_\mu$ with a value dependent on the orientation of the radical to the magnetic field B . Whereas in solution the anisotropic part of the tensor is averaged out, in a crystalline solid the full anisotropic nature can be seen. **Figure 7** shows FT- μ SR spectra from positive muons in naphthalene. The spectrum in (a) was obtained in acetone solution; the four lines are readily attributed to α and β radicals as

Figure 5 Muon spin spectra from positive muons stopped in 6,6-dimethylfulvene: (a) FT- μ SR spectrum showing the pairs of signals for each radical (a,a'; b,b') and that from muons stopped in diamagnetic environments (c); (b) ALC spectra: lower trace, experimental data; upper trace, numerical simulation. Figure 6 Coupling constants in mT and (spin populations) for the two Mu adducts to 6,6-dimethylfulvene. Spin populations were obtained using $Q = -2.6$ mT for α -protons and $Q = +2.925$ mT for Me protons. Reproduced with permission of the Royal Society of Chemistry from Rhodes CJ, Roduner E, Reid ID, and Azuma T (1991) *Journal of the Chemical Society, Chemical Communications* 208–209.

indicated in the figure. The spectrum in (b) results from a large (~ 25 mm) single crystal – it is quite evident that the simple solution spectrum has been replaced by a much more complicated system. Indeed, the four lines have been split into 32 because there are two molecules per unit cell, because the crystal environment halves the symmetry of the parent molecules, and because additions from above and below the molecule are also not symmetric. Nonetheless, the angular variation of the signals as the crystal was rotated about three orthogonal axes was mapped out and the hyperfine tensor was calculated for each of the 16 radicals. From symmetry and physical arguments, each was assigned to a specific addition site within the crystal. **Table 2** gives the results obtained for the tensor components.

The orientation of the radicals within the crystal was deduced to be very similar to that of the parent radicals, but effects from the crystal field on the hyperfine coupling constants were quite evident, particularly for the β radicals; note particularly the differences in the isotropic components for addition from both sides of the molecule. Comparison with an ENDOR study of α -hydronaphthyl radicals showed that the earlier work had not detected all the possible radicals and that the two identified arose

from addition at only one of the α sites; the ENDOR study did not see any β radicals. The reduced hyperfine coupling constants were ~ 10 – 20% larger than the proton values, although the comparison is not rigorous since the two studies were performed at greatly different temperatures.

As well as studies in condensed phases, μ SR can also be carried out in the gas phase using either surface muons at moderate pressures or decay muons at higher pressures. Experiments with ethylene gas at room temperature and pressures of 25, 35 and 50 atm revealed FT- μ SR signals that can readily be ascribed to the CH_2MuCH_2 radical. The resultant spectra are shown in **Figure 8**. The hyperfine coupling is 329.7 MHz, quite close to that found in liquid ethylene, and does not vary with pressure. The two radical signals are not of equal strength owing to the finite lifetime of the Mu precursor, which leads to dephasing of the muons and a corresponding loss of polarization. Calculations from the ratio of the polarizations of the two signals indicate a reaction rate coefficient of $16 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, compared to a value of $6 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ from relaxation measurements on the Mu signal in ethylene in a moderator gas at 295 K. The higher reaction rate coefficient implies a Mu temperature of around 500 K, showing that it has not completely thermalized before the reaction with the ethylene. The broad nature of the radical signals has been explained in terms of the spin-rotational interaction within the radical as it undergoes collisions within the gas.

Muonium and Radical Kinetics and Dynamics

The mass ratio between Mu and H is unparalleled and pronounced isotope effects are to be expected. In reaction kinetics experiments, for example, considerable kinetic isotope effects (KIE) may be found. Consider isotopic variations of the simple abstraction reaction

First, comparing the reaction with Mu instead of H, one should expect a trivial KIE of about 3 owing to the lower mass and hence higher thermal velocity of Mu. However, the lower mass can also lead to greater zero-point vibrational energy effects in the activated complex and on the product side, causing a higher barrier for the Mu reaction so that reaction of the heavier isotope may be faster. Finally, quantum-mechanical tunnelling is often considered important in H-atom reactions, so that the lighter mass of Mu should favour it in crossing reaction barriers.

Compared to H-atom reaction studies, Mu reactivity experiments are reasonably simple. Positive muons are stopped, in a low (< 0.8 mT) transverse field, in a moderator that produces a high yield of Mu, doped with

Figure 7 FT-μSR spectra obtained for positive muons implanted in naphthalene samples: (a) in saturated acetone solution; (b) in a large single crystal. Reproduced with permission from Reid ID and Roduner E (1991) *Structural Chemistry* 2: 419–431.

varying concentrations $[X_2]$ of the reactant. Exponential relaxation of the coherent Mu precession signal is attributed to randomly occurring chemical reactions that transfer the muon to a different magnetic state where its precession frequency is significantly different. There is thus a linear relationship between the relaxation rate λ

and $[X_2]$, leading directly to the thermally averaged bimolecular reaction rate constant k :

$$\lambda([X_2]) = \lambda(0) + k[X_2] \quad [8]$$

where $\lambda(0)$ is the relaxation rate for $[X_2] = 0$.

Table 2 Principal values of reduced hyperfine coupling tensors for Mu-substituted radicals in single-crystal naphthalene ($A'_{ij} = A'_{iso} + B'_{ij}$). Also given are the isotropic solution couplings and the tensors obtained for the CH₂ protons of analogous hydrogen radicals by ENDOR spectroscopy

Many studies have been undertaken of such reactions, for example reaction of Mu with the halogen gases (F₂, Cl₂ and Br₂). For both F₂ and Cl₂ the data showed a significantly shallower slope in the Arrhenius plots of k vs T at temperatures below 200 K, clear evidence for tunnelling dominating the reaction in this region. This feature is absent from comparable H-atom reaction data. For Br₂, on the other hand, a negative

slope was observed, indicating a negative activation energy E_a . In these highly exothermic reactions, the barrier is early on the reaction path and so the transition state approximates a slightly perturbed reactant molecule whose vibrations are only weakly dependent on the isotopic substitution. There may, however, still be a significant effect in the transmission coefficients for tunnelling, $\kappa_{\text{H},\text{Mu}}$. Table 3 summarizes some of the results obtained in this study and shows that there are indeed significant tunnelling effects even at the higher temperatures.

On the other hand, there are significant zero-point energy effects in the reaction of Mu with H₂ and D₂, since these reactions are highly endothermic ($\Delta H_R^0 = 32$ and 38 kJ mol⁻¹, respectively) so the vibrationally adiabatic barrier is late on the reaction path. The potential energy surface of the H₃ system is known to a high accuracy, so comparison of the results for these reactions with various theoretical treatments should help elucidate the extent to which the above effects are important and how well they can be predicted theoretically. Such measurements have been carried out over the temperature ranges 473–843 K and 598–843 K, respectively. Comparison with theoretical results showed that 3D quantum coupled states (CS) calculations of the reactions fit the data much better than improved canonical variation theory treatments, verifying the validity of both the potential energy surface and the CS treatment.

Studies of hydrogen KIE often involve reactions where a reagent attacks a H—R/D—R bond, transferring the isotope atom, whereas in Mu reactivity studies muonium is normally the attacking species. One example where Mu is thought to be transferred is the reaction of cyclohexadienyl radicals with 2,3-dimethyl-1,3-butadiene (DMBD).

In both pure benzene and pure DMBD, just one radical is observed via TF- μ SR, with narrow lines ($\lambda_0 < 0.5 \mu\text{s}^{-1}$). However, in binary mixtures of the

compounds or in three-component mixtures with cyclohexane, the cyclohexadienyl lines broaden with increasing DMBD concentration while the line width of the allyl-type radical remains narrow. This obviously indicates a reaction of the cyclohexadienyl radical with DMBD. From the variation of line width with concentration (eqn [8]) a reaction rate constant k_{Mu} of $0.95 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ was obtained at 293 K. The protiated cyclohexadienyl radical has been observed in time-resolved EPR experiments, but no significant reaction with DMBD was seen, with an upper limit to k_{H} of $\sim 12 \text{ M}^{-1} \text{ s}^{-1}$. This yields an enormous KIE: $k_{\text{Mu}}/k_{\text{H}} \gtrsim 7.5 \times 10^4$ at room temperature. For such an affect Mu must be directly involved in the reaction and it is believed the scheme is:

Reaction of $\text{C}_6\text{H}_6\text{Mu}$ is favoured over C_6H_7 primarily because of its higher zero point vibrational energy, but tunnelling is also involved.

Other μSR methods can also be used to probe reactivity. For example, muon relaxation in longitudinal fields has recently been used to study the gas-phase reaction of the muonated ethyl radical with oxygen. Analysis of the results enabled a separation of the effects of chemical reaction and spin-exchange, leading to values of $k_{\text{ch}} = 8.4(3) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and $k_{\text{ex}} = 2.8(2) \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively, at room temperature. It is striking that the chemical reaction rate is so much smaller than the spin-exchange rate, but this is explained by the anisotropy of the potential energy surface for chemical reaction leading to successful bond formation.

Dynamic effects in radicals also can be studied by μSR . Particularly useful is the $\Delta M = 1$ ALC- μSR resonance, which is only observable when there is anisotropy in the hyperfine coupling. Phenomenologically it can be thought of as occurring when the lower frequency $\nu_{\text{R-}}$ in eqn [4] passes through zero, i.e. a field where $\nu_{\text{H}} \sim \frac{1}{2} A_{\text{H}}$ (eqn [6]). Here a component of the hyperfine field is nullified by the external field and any anisotropy is seen by the muon as a transverse field, which causes it to precess and thus depolarize, leading to an observable resonance. Since the hyperfine tensor is anisotropic, this resonance should be seen unless the radicals are reorientating so fast as to average out the anisotropy. This was found to be the case for cyclohexadienyl radicals in a benzene monolayer on silica, for example, where the lack of the resonance down to 139 K

was taken as evidence that the radicals remained mobile on the surface.

A further study used this resonance to ascertain the anisotropic components of the hyperfine coupling in the radicals formed by irradiating bicyclo[2.2.1]hept-2-ene (norbornene) in its plastic phase. The tensor had already been derived from a single-crystal FT- μSR investigation, but the ALC experiment was able to determine the (axial) anisotropy in a powder sample from the asymmetry of the shape of the resonance. The results agreed well with the FT- μSR data and confirmed effective partial averaging above T_{c} (129 K) and a rapid approach to complete isotropy at T_{m} (320 K).

Potential and Limitations of the Muon as a Probe

Spin Polarization and Usable Field Range

Clearly, for a magnetic resonance type technique, the availability of a probe with a polarization close to 100% under all conditions is an immense advantage. Most techniques must work with Boltzmann populations, corresponding to polarizations of typically 10^{-5} for protons and 10^{-3} for electrons in commonly available magnetic fields and at room temperature. Muons have their full polarization independently of sample temperature and magnetic field and are therefore ideal probes, especially at low or zero field and at high temperatures.

Longitudinal fields up to about 7 T have been used for ALC- μSR experiments. TF- μSR has been limited by the routinely available time resolution to $\sim 3\text{--}4$ T, corresponding to a Zeeman frequency of about 500 MHz. An important advantage over conventional magnetic resonance, however, is the availability of a fully polarized probe in *zero* field where additional information becomes accessible.

Time Resolution

Magnetic resonance techniques in time-resolved mode normally create transverse magnetization by application of a preparation pulse. This limits time resolution to typically 50 ns in EPR, and to several hundred nanoseconds in NMR, although a combination with optical techniques can break this limitation.

Since muons can be injected with their spins transverse to the external field, a preparation pulse is not

necessary and time resolution is limited only to the accuracy with which t_0 , the entrance time of the muon into the sample, can be measured. This is typically half a nanosecond when working with individual muons, and if needed it can be improved by a factor of about 5 at the cost of counting statistics.

Frequency Resolution

The muon lifetime of $2.2\ \mu\text{s}$ sets a natural limit of 0.45 MHz on the widths of μSR lines. The nominal frequency resolution is given by the inverse length of the histogram. Using pulsed machines it is not uncommon to observe the FID over a time window of $20\ \mu\text{s}$, which leads to a nominal resolution of 0.05 MHz.

Time Window

The accessible time window for processes that can be observed directly extends between typically 10^{-9} s and 10^{-5} s . The limits are determined by the same parameters as time and frequency resolution. The windows accessible to NMR and EPR are thus extended considerably towards shorter times.

The time window can be extended to even shorter times if there is a muonium precursor state. Evolution of spin polarization in Mu occurs partly at frequencies near the Mu hyperfine frequency (4463 MHz in vacuum, broken arrows in **Figure 2**), which sets the timescale for loss of phase coherence during formation of the observed muonated species. The formation process can be studied indirectly in transverse fields by interpretation of shifts in the initial phase and concomitant loss of amplitude. Thus, processes occurring on a timescale down to 10 ps can be analysed, but the results rely on the validity of the underlying model.

The Muon as a Local Probe

In the same sense as nuclei in conventional magnetic resonance techniques, the muon is a local probe. While, for example, magnetization measurements give an integral response, the local magnetic probe may precess at different frequencies when it sits at different sites. The advantage of the muon is that it can be implanted in any material, including those that contain no other suitable NMR-active nuclei. For organic muonated radicals, the stopping site can be derived with confidence by analogy with the known chemistry of hydrogen atoms. In organic solids it is in general an interstitial site – this may be a nonbonding electron pair if oxygen or nitrogen are present. In semiconductors, some muons come to rest at bond centre sites. There are, however, many examples of materials where a firm determination of the stopping site is difficult.

It is important to consider to what extent the muon is also a perturbing probe. In comparison with the analogous

proton or hydrogen defects, the differences are certainly small. The structure and properties of muonated radicals are very similar to those of their hydrogen analogues and therefore well understood. On the other hand, a radical could be viewed as a strongly perturbed diamagnetic precursor molecule, which demonstrates how much the probe can change the electronic structure. In crystalline solids the properties measured are often not the same as those in the absence of the probe. It is clear, for example, that in a metal the positive charge of the muon causes charge polarization of the surroundings, leading to some structural relaxation.

Sensitivity

Both the high spin polarization of the muon and the single-event detection technique lead to a high sensitivity of the muon spin resonance methods. The total number of muons needed for a routine μSR experiment in transverse fields is of the order of 10^7 , while X-band ESR at room temperature needs about 10^{11} unpaired electrons, and single-scan proton NMR needs on the order of 10^{17} spins to allow the observation of a narrow, unsplit signal. This sensitivity is particularly crucial for the observation of surface-adsorbed organic free radicals – it is difficult to maintain the minimum concentration for EPR detection under conditions where the radicals are mobile since they disappear via bimolecular termination reactions, whereas in TF- μSR one has a single muonated radical at a time in the entire sample. This allows adsorbed radicals to be observed up to temperatures where they desorb or undergo catalytic reactions. Termination reactions also represent a severe limitation to kinetic work in liquid solutions and in the gas phase, so the fact that the μSR technique guarantees ideal pseudo-first-order kinetics is clearly advantageous.

Introduction

NMR spectroscopy, from its inception, has been an important tool in the elucidation of molecular structures. With the introduction of techniques like Fourier transformation (FT) and dispersion of resonances into a second frequency dimension (2D NMR), NMR has found applications in the study of increasingly more complex molecules. One such application is in the study of the structure and dynamics of biological macromolecules such as proteins and nucleic acids. The successful use of NMR spectroscopy for determining the structures of biological macromolecules has triggered immense interest in the development of countless multidimensional NMR (nD NMR, where $n > 2$) methods that contribute to better understanding of the structure and structure-related properties of biomacromolecules. Because of the

large size and complex structures of biomacromolecules, their 1D and 2D NMR spectra are extremely complex and their resonance assignments are difficult to determine, even using 2D NMR methods. To overcome these difficulties, spectroscopists have extended the use of multidimensional spectroscopy to higher and higher dimensions.

Fundamentals of nD NMR

General Sequences for Collection of 3D NMR Spectra

The first nD NMR spectroscopy methods were based on proton detection because of its high natural abundance. The fact that a single type of nucleus, that is protons, was involved simplified the instrument hardware needs and the experimental setup; an instrument with only a single radiofrequency (RF) was needed, and only calibrations on that channel were required. Hypothetical pulse sequence diagrams for collection of 1D, 2D, 3D, and nD NMR spectra are illustrated in **Figure 1**. A 1D NMR experiment has at minimum two components: preparation of the spins and detection. In its simplest form, the preparation period contains a relaxation delay (to permit the spins to recover from prior operations) and a pulse to produce detectable signal components perpendicular to the magnetic field. A 2D NMR experiment (**Figure 1(b)**) has four components: preparation, evolution, mixing, and detection; it is formed by incorporating an evolution time (t_1) and mixing period into the corresponding 1D experiment (**Figure 1(a)**). The pulse sequence in **Figure 1(b)** is for a nuclear Overhauser enhancement spectroscopy (NOESY) experiment, and the coherence transfer period involves a (90° –mix– 90°) sequence to accomplish coherence transfer between protons that are close in space. In some experiments, a single RF pulse can serve as a mixing period to transfer coherence between two nuclei whose precessions are detected during t_1 and t_2 . A 2D NMR experiment can be extended to a 3D NMR experiment (**Figure 1(c)**) by

Figure 1 Schematic diagrams of pulse sequences for n D NMR experiments: (a) 1D NMR, (b) 2D NMR, (c) 3D NMR, and (d) n D NMR. Sequential incorporations of evolution times (t_{n-1}) produce n D NMR experiments; by convention, the signal is directly detected during the t_n period.

inserting an additional (evolution–mixing) sequence to encode the chemical shift of a third nucleus (or some other NMR parameter) of interest; a series of 2D experiments is performed while systematically incrementing a t_2 evolution time delay. In theory, the methodology can be extended to n arbitrary dimensions by incorporating $(n-1)$ evolution and mixing periods. In its simplest implementation, each of the evolution times is incremented separately. At the end of the (evolution–mix) $_{(n-1)}$ series of delays, the resonances are detected; these are modulated by the product of relevant NMR parameters detected during the $(n-1)$ dimensions. For practical reasons described at the end of this article, this straightforward implementation of n D NMR is limited to 3D NMR spectroscopy.

The homonuclear correlation spectrum produced by the 3D pulse sequence in **Figure 1(c)** is illustrated in **Figure 2(a)**, where hypothetical correlations among three protons A, M, and X are displayed. In theory, if all permutations of coherence transfers occur during each of the mixing periods, then an m -spin system observed using n D NMR will produce m^n sets of correlations; in **Figure 2(a)**, a hypothetical 3D NMR spectrum of a three-spin system shows 27 possible sets correlations. To

complicate the spectra further, if there is J -coupling among the spins, then a single correlation X in **Figure 2(b)** will, on careful examination, exhibit a coupling pattern that will resemble that shown in **Figure 2(c)**. For these reasons, the simplification expected in proton homonuclear n D NMR is not achieved, and the simplest application of the pulse sequence scheme in **Figure 1** is rarely used. In practice, selective inversion pulses (to remove some of the coupling interaction) can be used to simplify homonuclear 2D and 3D NMR spectra; however, these methods have rarely been used for n D NMR with n greater than 2.

Heteronuclear 3D NMR Spectroscopy via J -Coupling

Eventually, measurement of NMR parameters for other important nuclei like ^{13}C and ^{15}N (1.1 and 0.37% natural abundance, respectively) was incorporated into n D NMR spectroscopy. These methods became especially popular for studying biomacromolecules once molecular biology techniques became widespread for uniform isotopic labeling of biomacromolecules, as this helped to overcome sensitivity limitations imposed by the low natural

Figure 2 A hypothetical homonuclear 3D NMR spectrum from an AMX spin system showing (a) all the possible correlations if all coherence transfer paths are possible during each of the mixing periods; (b) if a single correlation X is extracted and examined for detail, then the cross-peak pattern in (c) will be observed if J_{AM} , J_{AX} , and J_{MX} are all nonzero. The simplification hoped for in a 3D NMR experiment will not be achieved because of all these possible coupling interactions. Adapted from Griesinger C, Soerensen OW, and Ernst RR (1989) Three-dimensional Fourier spectroscopy. Application to high-resolution NMR. *Journal of Magnetic Resonance* 84: 14–63.

abundance of these heteronuclei. New dimensions in the NMR spectra can be added by frequency encoding the labeled nuclei (e.g., ^{13}C and ^{15}N) during dedicated evolution times, through efficient coherence transfer between nuclei.

The first option for dispersing the resonances into the third dimension was to create a 3D experiment by concatenating two 2D experiments as illustrated in **Figure 3**. Here, a hypothetical structure fragment $-\text{C}_\text{A}\text{H}-\text{C}_\text{B}\text{H}-\text{C}_\text{C}\text{H}-$ shown at the top of the figure produces a COSY (correlation spectroscopy) 2D spectrum with correlations among all the mutually coupled ^1H spins (**Figure 3a**), whereas the HMQC (heteronuclear multiple quantum coherence) 2D spectrum produces correlations between the resonances of directly attached ^{13}C and ^1H nuclei (**Figure 3(b)**). If the HMQC pulse sequence is used to generate coherence on ^1H nuclei in place of the first 90° pulse in the COSY experiment, the COSY evolution period becomes t_2 in a 3D experiment and the 3D spectrum in **Figure 3(c)** is produced. This double resonance 3D experiment provides the combined information of two 2D experiments in a single 3D experiment. Spectral simplification is achieved by dispersing the COSY correlations into a third dimension based on ^{13}C chemical shift. At each ^{13}C chemical shift, only the COSY correlations to the directly attached protons are observed. Coherence transfer is accomplished first using one-bond C–H couplings ($^1J_{\text{CH}}$, typically 120–170 Hz) during the HMQC part of the sequence, and then by two- and three-bond couplings among protons ($^{2,3}J_{\text{HH}}$, typically 1–10 Hz). For relatively small molecules, to a first

approximation, the sensitivity of these experiments is similar to the corresponding heteronuclear 2D experiment (in this example, the HMQC experiment). Variations in concatenated 2D experiments like this were first used to study low molecular weight polypeptides. However, for very large molecules (approximately $> 5 \text{ kD}$) such as proteins, these types of experiments suffer from a significant amount of signal loss due to the long delays involved in the coherence transfer based on small $^{2,3}J_{\text{HH}}$. Typically, coherence transfer occurs on the timescale of $1/J$ (100–500 ms for protons), and the relaxation times of large macromolecules are typically less than 100 ms.

To circumvent relaxation problems, heteronuclear triple-resonance 3D experiments were developed. Triple-resonance 3D experiments are generally performed on uniformly ^{13}C - and ^{15}N -labeled molecules; magnetization is transferred from the first to a second and then to a third nucleus and then transferred back to the first nucleus before the signal is detected. In structural biology this general class of experiments is known as an ‘out-and-back’ method. The first nucleus, which is the source of magnetization, is usually ^1H , whereas the second and third nuclei are heteroatoms such as ^{13}C and ^{15}N . The coherence transfer is typically accomplished by sequential INEPT (insensitive nuclei enhanced by polarization transfer) pulse sequences using sequential one-bond couplings. This is illustrated in **Figure 4** by a greatly simplified version of the HNC0 pulse sequence, which is one of the experiments used in structural biology to obtain resonance assignments and atomic connectivity information on the polyamide backbone of proteins. The

Figure 3 Construction of a heteronuclear 3D NMR experiment by concatenation of two 2D NMR experiments, and the anticipated spectrum from a $\text{CH}_A\text{-CH}_B\text{-CH}_C$ structure fragment: (a) simple COSY spectrum with a schematic of the 1D ^1H spectrum across the top, (b) ^1H - ^{13}C HMQC spectrum with a schematic of the 1D ^{13}C spectrum across the top showing C_A , C_B , and C_C resonances, and (c) corresponding HMQC-COSY spectrum obtained by replacing the COSY preparation period with the pulse sequence elements of the HMQC spectrum.

pulse sequence name (acronym) is derived from the letters representing the sequential atoms in the structure that form the coherence transfer pathway. Here, after a relaxation delay (A), an $\text{H} \rightarrow \text{N}$ INEPT transfer is accomplished (period B, $\tau = 1/(4 \times ^1J_{\text{NH}})$). During the first evolution period t_1 (C), ^{15}N chemical shifts are encoded; the three 180° pulses in the middle of the t_1 evolution period serve to decouple the three nuclei (^1H s, carbonyl carbon, and C_α s). During period D, ^{15}N antiphase magnetization with regard to coupling with $^{13}\text{C}=\text{O}$ develops; the $90^\circ_{\text{C}=\text{O}}$ pulse creates ^{15}N - ^{13}C two-spin coherence, which is modulated by the $^{13}\text{C}=\text{O}$ chemical shift during t_2 (E); 180° pulses to ^{15}N and $^{13}\text{C}_\alpha$ remove the effects of coupling to those nuclei in the t_2 ($^{13}\text{C}=\text{O}$ chemical shift) dimension. Periods F and G reverse the coherence transfer achieved during the first part of the

sequence, leaving the coherence on ^1H for sensitive detection of the NMR signal during period H. In currently used versions of these pulse sequences, coherence selection and cancellation of artifact signals from imperfect pulses, resonance offset effects, and so on are achieved with pulsed field gradients (gradients not shown). These types of experiments minimize the signal loss, because there is efficient transfer of coherence using large one-bond J -couplings. Additionally, significant spectral simplification is achieved by dispersing the resonance into the relatively large second and third dimensions based on ^{13}C (amide carbonyl) and ^{15}N (amide nitrogen) chemical shifts. The resulting spectrum (**Figure 5(a)**) is further simplified because peaks arise only from the structure fragment where the three nuclei are interacting through coupling. Because the peak dispersion is so great and the 3D experiments are so time consuming, narrow spectral windows are used; this results in extensive folding in the indirect detection dimensions (see the section 'Experimental aspects of nD NMR'). Consequently, extensive folding is observed; the HNCOSY spectrum in **Figure 5(a)** contains eight separate sets of C-H correlations (from eight separate H-N-C(O)-structure fragments) in a single ^{15}N chemical shift plane, instead of the single expected set of correlations.

The 3D NMR pulse sequences also provide decoupling in the indirectly detected dimensions so that the correlations appear as singlets in the f_1 and f_2 dimensions. Since the experiments are usually performed on biopolymers uniformly labeled with ^{13}C and ^{15}N , the experiments have the sensitivity approaching that of standard proton NMR spectra (although some signal loss arises due to cumulative errors from imperfect pulses, incomplete coherence transfer, and partial relaxation).

Applications of nD NMR

An enormous array of nD NMR experiments have been devised to assign resonances of biological macromolecules. The most significant efforts have focused on studies of proteins where methods have been devised to determine the primary structures of complex proteins, identify secondary and tertiary protein structures, and study protein molecular dynamics. Early methods have found applications in the study of proteins with molecular weight up to approximately 50 kDa; recently developed methodology has extended the use of these methods to proteins with molecular weight 100–150 kDa. Methodology similar to that used for studying proteins has evolved and is commonly used to study small fragments (50–100 base pairs) of RNA and DNA. Protein 3D NMR methodology has also been adapted to study the complex structures of synthetic macromolecules.

Figure 4 Diagram of an HNCO experiment that is representative of the pulse sequences used in studies of protein structure. The arrows on the amide structure at the top illustrate the coherence transfer steps in the pulse sequence. Open and filled rectangles in the pulse sequence diagram indicate 180° and 90° pulses, respectively. (1995) *Journal of Biomolecular NMR* 5: 110–121.

Protein Structure Determination

In practice, the results from several 3D NMR experiments are combined to obtain the total structure of a biological macromolecule. These pulse sequences resemble the HNCO 3D NMR sequence shown in **Figure 4**, but different permutations of pulses are used, which are selective for NH, H_α , C_α , CO ($\text{C}=\text{O}$ or C'), C_β , and so on. The sequences generally start out with the large polarization of protons from either NH or H_α . The names of the sequences trace out the paths of coherence transfer during the pulse sequence. Some of these sequences are shown in **Figure 6** along with a schematic illustration of the protein structure information they provide.

The spectrum in **Figure 5(a)** shows the results from an HNCO experiment where the pulse sequence in **Figure 4** is used to relate the shifts of the amide $^1\text{H}_\text{N}$, amide ^{15}N , and $\text{C}=\text{O}$ ^{13}C to identify all of the unique protein structure connectivities in **Figure 6(a)**. A second 3D experiment relates the shifts of the amide $^1\text{H}_\text{N}$, amide ^{15}N , and $^{13}\text{C}_\alpha$ to identify all of the unique protein structure connectivities within an amino acid fragment as shown in **Figure 6(b)**; this experiment also often provides weak correlations (via $^2\text{J}_{\text{NC}=\text{O}}$ polarization transfer) to the amide ^{15}N of the next amino acid fragment. Typical results are shown in **Figure 6(b)**, where most $^1\text{H}_\text{N}$ chemical shifts are correlated with two amide ^{15}N chemical shifts, a strong correlation from the large one-bond $^1\text{J}_{\text{NC}=\text{O}}$ and a weaker correlation from the smaller two-bond $^2\text{J}_{\text{NC}=\text{O}}$. A third 3D experiment, HCACO, relates the H_α - C_α -CO chemical shifts and identifies those structure fragments (**Figure 6(c)**). A fourth 3D experiment, the HCA(CO)N pulse sequence, relates the nuclei highlighted on the

Figure 6 Schematic illustration of a protein backbone structure (top) and the corresponding structure units identified by: (a) HNCO, (b) HNCA, (c) HCACO, (d) ^{15}N -TOCSY-HSQC, and (e) HCA(CO)N 3D NMR experiments.

structure fragment in **Figure 6(e)**; the significance of the parentheses around CO in the name of this pulse sequence is that the carbonyl ^{13}C serves as a link in the sequential magnetization transfer path, but its shift is not encoded in an evolution period. The combination of correlations (**Figure 5**) from a number of 3D NMR experiments like those shown diagrammatically in **Figure 6** provides sufficient redundant information to identify the sequential resonance assignments and primary structures of complex proteins with molecular weight up to several tens of kilodaltons. Dozens of specific sequences and their variations have been devised to provide extensive information on both polyamide backbone and amino acid side-chain structure and resonance assignments. Multidimensional experiments of complex proteins provide enormous spectral dispersion so that individual proton resonances can be resolved and the correlations found in these spectra provide unique proton resonance assignments.

Once complete resonance assignments are obtained, additional 3D experiments incorporating H–H NOESY-type correlations provide elucidation of inter-residue through-space H–H interactions, and provide information on secondary and tertiary protein structures.

Solid state 3D NMR techniques, incorporating cross-polarization, dipolar decoupling, and magic angle spinning, but using J coupling-modulated coherence transfer steps analogous to those found in the solution 3D NMR methods described above, have recently been reported for the structure determination of proteins in crystalline solids.

As NMR spectroscopy can now be applied to identify the structures of biomacromolecules with molecular

weights in the range of tens of kilodaltons, scientists are trying to find ways to streamline the process of solving the structures of larger and more complex biomacromolecules. One method of simplifying the resolution of resonances and the process of assigning the resonances recognizes that redundant information is present in several 3D NMR experiments; therefore, several 3D NMR experiments can be combined to produce higher dimensional $n\text{D}$ NMR experiments, where $n > 3$ with additional desired correlations.

Collection of Protein $n\text{D}$ NMR Spectra

The concept of combining multiple 3D NMR experiments, or adding additional coherence transfer steps and evolution times, to generate $n\text{D}$ NMR techniques is obvious; experiments with n as high as 11 have been reported. However, the straightforward application of the methodology of systematically sampling all permutations of evolution times has a practical limit of $n\text{D}$ NMR with $n = 3$ or 4. If it requires 24 h to collect a typical 3D NMR spectrum, even with standard shortcuts and reducing digital resolution by sampling relatively few data points in the indirectly detected dimensions, collection of a 4D NMR data set can take weeks. Because of these exceedingly long data collection times, shortcuts are required to collect higher dimensional spectra. The use of new sparse sampling techniques has now become commonplace in applications involving protein structure determinations. In addition, methods for simultaneously incrementing two or more evolution times (G-matrix FT NMR or GFT NMR and projection reconstruction

methods) have been devised. With these methods, it becomes possible to obtain nuclear correlations from nD NMR spectra and, in principle at least, to identify the complete bonding network in a complex molecule from a single NMR experiment. There is currently an enormous amount of activity in this area, especially as applied to protein structure determinations.

Methods for Producing nD Correlation Spectra of Very Large Proteins

The methods described for J -modulated coherence transfer have been applied to structural studies of molecules with molecular weights in the tens of kilodaltons. When molecular weights are higher, proton–proton dipole–dipole relaxation broadens the resonance line widths and renders correlations undetectable even when larger one-bond J -couplings are used for coherence transfer. To minimize the effects of proton–proton dipole–dipole relaxation broadening, extensive random deuteration of the protein is performed so that isolated protons are studied. The loss in sensitivity by replacement of 80–90% of protons with deuterium is usually more than offset by increased signal strength from line narrowing achieved by replacement of many T_{ρ}^{HH} interactions with T_{ρ}^{HD} , which is approximately 50-fold longer. Even with the aid of partial deuteration, the molecular weight limit for protein NMR studies is on the order of 50–70 kDa.

Pervushin et al. recognized that the individual multiplet components of an X–H spin system in 2D NMR spectra of biomacromolecules have very different transverse relaxation rates ($1/T_2$) and that the resulting decoupled 2D X–H correlation has a composite line width determined by all these relaxation rates (**Figure 7(a)**). **Figure 7(b)** illustrates the four possible multiplet components for a fully coupled two-spin X–H heteronuclear correlation. Here, three of the four multiplet components exhibit T_2 relaxation broadening in f_1 and f_2 , whereas the fourth component (lower right) remains relatively sharp. The lengthening of T_2 is derived from interference between dipole–dipole and chemical shift anisotropy contributions to the relaxation mechanism of this signal component. This phenomenon has been called the transverse relaxation optimized spectroscopy (TROSY) effect. For the TROSY effect to become significant, the chemical shift anisotropy must be large. The lengthening of T_2 is thought to be optimal for producing narrow correlations at magnetic fields producing ^1H resonance frequencies near 1 GHz. A TROSY pulse sequence was devised to selectively detect this sharp resonance component (**Figure 7(c)**) while using pulsed field gradients to suppress the remaining signal components. Since the initial report of TROSY, the methodology has been found to produce nD spectra for proteins in the molecular

Figure 7 Two-dimensional contour plots of ^1H -detected ^1H – ^{15}N COSY spectra showing cross-peaks from an indole ^{15}N – ^1H spin system from a 2 mM solution of a uniformly ^{15}N -labeled 14-base pair DNA duplex: (a) conventional experiment with broadband decoupling of ^1H during t_1 and ^{15}N during t_2 , (b) experiment with full coupling in t_1 and t_2 , and (c) TROSY spectrum showing selective detection of the slow-relaxing (in both t_1 and t_2 dimensions) multiplet component. Reproduced from Pervushin K et al. (1997) *Proceedings of the National Academy of Science USA* 94: 12366–12371.

weight range up to 150 kDa. The most used nD NMR pulse sequences for protein structure studies have been adapted for TROSY detection.

Internuclear Distance Determination

Most of the aforementioned experiments involve coherence transfer using J -modulated interactions between nuclei, and provide information about the atomic bonding

within a complex molecule. It is equally important to obtain structure information on nonbonding interactions between atoms in order to obtain secondary and tertiary structure information about complex molecules. For this purpose, NOE-based mixing periods are inserted into nD NMR experiments. Most commonly, at least one dimension is encoded with the shift of a heteronucleus ($X = {}^{13}\text{C}$ or ${}^{15}\text{N}$ for proteins) to provide large chemical shift dispersion. Although heteronuclear NOEs are observable in the spectra of small molecules, these NOEs approach zero for typical proteins. The vast majority of protein NMR experiments seek to identify ${}^1\text{H}$ - ${}^1\text{H}$ homonuclear NOE interactions, and ${}^1\text{H}$ - ${}^{13}\text{C}$ -HSQC-NOESY and ${}^1\text{H}$ - ${}^{15}\text{N}$ -HSQC-NOESY experiments are often used for this purpose. Thus, at least two dimensions in an nD NMR experiment encode ${}^1\text{H}$ chemical shifts and produce correlations between two nuclei H_a and H_b that are close in space, with dispersion in a third dimension based on the chemical shift of an attached ${}^{13}\text{C}$ or ${}^{15}\text{N}$. The form of the spectrum is identical to that shown in Figure 3(c), but with ${}^1\text{H}$ - ${}^1\text{H}$ correlations determined by through-space NOE interactions rather than J_{HH} coupling interactions.

A plot of the cross-peak volume versus mixing time in a NOESY spectrum is a bi-exponential function with an increasing time constant $T_{1a,b}$ dependent on r^{-6} , where r is the internuclear distance between H_a and H_b , and a decreasing exponential dependent on the total relaxation time T_1 for the observed nucleus. In early applications of NOESY experiments, researchers attempted to extract the individual NOE buildup rates between pairs of nuclei, by obtaining either a series of spectra from experiments run at short mixing time or a single NOESY spectrum obtained with a short (20–50 ms) mixing time. Under these conditions, it was assumed the cross-peak decay was insignificant, the initial NOE buildup was linear (valid for the early part of an exponential curve), and the ratio of peak volumes was directly related to the relative NOE buildup rates, and thus the ratios of r^{-6} . Attempts were then made to relate the relative cross-peak intensities to the relative NOE buildup rates, and ultimately to the relative H–H internuclear distances. These earlier attempts to use quantitative NOEs to obtain quantitative protein H–H internuclear distances were problematic. Now, NOESY data are used to determine qualitative constraints for internuclear distances as near, medium, and far ($>5 \text{ \AA}$). Even this qualitative distance information is tremendously useful when employed in conjunction with molecular modeling software to determine protein structures.

Although NOE-based distance constraints are useful for protons that are $<5 \text{ \AA}$ apart, the data are not useful for long-range distances, as the strength of the NOE interaction is inversely related to the sixth power of the internuclear distance and falls off quite rapidly as the internuclear distance is increased. This relationship

particularly imposes a limitation on determining the tertiary folding, which primarily influences long-range distance constraints. Measurement of residual dipolar coupling (RDC) is a remedy to overcome this limitation and can provide distance constraints over longer distances than those obtained from NOESY data.

The dipolar (through-space) coupling between two nuclear spins depends on the distance between the two spins and the orientation of their internuclear vector with respect to the magnetic field. The dipolar interaction is given by:

$$H_D = -S[\gamma_i\gamma_j\hbar/(2\pi^2r^3)][(3\cos^2\theta - 1)/2]I_{zi}I_{zj}$$

where r is the internuclear distance between the spins, θ the angle between the internuclear vector and the applied magnetic field, and S is an order parameter that describes the degree of orientation. In *isotropic* solution (where protein molecules are not oriented in a magnetic field), the angular term averages to zero ($S=0$) because of the tumbling of the protein molecules, and the splitting due to dipolar interaction is not observed. When the molecule is oriented in the magnetic field, this interaction contributes to the splitting of NMR resonances in addition to the splitting caused by the scalar (J) coupling for bonded nuclei. If the molecules can be partially oriented with respect to the magnetic field, then the dipolar coupling will have a small, but measurable residual value, known as RDC. In the coupled NMR spectrum, the RDC will be observed as the splitting of resonances that vary from their normal value due to scalar couplings. The conditions that cause partial orientation include high magnetic field (similar to the fields used for high-resolution NMR experiments) and either a large anisotropic magnetic susceptibility for the molecule or a partial alignment in anisotropic media. In partially oriented media, the splittings due to RDC are field dependent, and this field dependence of the RDC allows separation of its contribution from that of the scalar coupling contribution (which is field independent) to the observed splitting.

The measurement of RDC was first demonstrated with cyanometmyoglobin, a protein with highly anisotropic paramagnetic susceptibility, which spontaneously orients itself in a high magnetic field (17.5 T). Later, it was shown that proteins can be partially oriented in external alignment media that are compatible with biomolecules. The first of this kind was a liquid crystalline solvent, a mixture of phospholipids, which at a specific composition and temperature forms an anisotropic phase referred to as a bicelle. Stretched polyacrylamide gel, bacteriophage Pf1, and cellulose fibers are other examples of alignment media. The choice of alignment medium depends on the compatibility of the medium with the biomolecules at the working temperature and pH, and the net charge of the biomolecule at the working pH.

A specially designed coupled 2D HSQC experiment, which allows pure dipolar splitting evolution for half the period and chemical shift plus dipolar splitting evolution for the other half, is used to measure RDCs. A coupled HSQC spectrum is first collected in isotropic solution to measure the splittings arising from scalar coupling between two directly bonded nuclei. The splitting is again measured in the anisotropic medium that now has contribution from both the scalar coupling and the RDC. The value for the RDC is then extracted from the difference between the splittings observed in alignment medium and in isotropic solution.

The relative values of RDC for a set of singly bonded nuclear pairs, for example amide protons (^1H – ^{15}N), depend on their relative orientation with respect to the axis of the alignment tensor, as the distance between nuclear pairs, for example two ^1H – ^{15}N pairs, is relatively constant. Thus, the relative orientation of two-bond vectors can be obtained from RDC values.

By using RDCs, internuclear distances up to 12 Å can be measured as the distance dependence is $1/r^3$ as opposed to $1/r^6$ for the NOE. The structures calculated from RDCs greatly improve the accuracy and precision of protein and nucleic acid structures derived from NMR. The use of RDCs has also become popular for determining the structures of small molecules.

Protein Dynamics

Many functions of a protein depend on its molecular motion or dynamics. Understanding the dynamics of proteins is therefore important in order to understand the functions of proteins such as binding events, folding, and unfolding. Evidence of protein dynamics was first observed by Wüthrich et al. during the study of the variation in the chemical shift and intensities of ^1H resonances of aromatic side chains in small globular protein as a function of temperature. In addition to determining the structure of proteins, modern high-resolution nD NMR spectroscopy can also shed light on protein dynamics. Proteins have many different types of motions associated with a wide range of timescales. Surface atoms interact with water in the picosecond range, whereas local motions such as the rotation of small groups on proteins that move as a single entity (e.g., methyl group and aromatic ring rotation) fall in the nanosecond range and local folding and unfolding and catalysis-related motions require times on the order of microseconds to milliseconds. Because of this range of protein dynamics, it is necessary to study the motions of proteins with different NMR methods, depending on their sensitivity to the motional regime of interest.

Information on fast motions that fall in the picosecond to nanosecond range can be obtained from ^{15}N T_1 relaxation

(related to return of M_z to its initial value of M_0 via spin lattice relaxation), whereas T_2 relaxation (related to decay of the M_{xy} magnetization component to its initial value of zero, via spin–spin or transverse relaxation) is sensitive to motion in the microsecond to millisecond timescale. Ordinarily, T_1 relaxation times are measured by the inversion recovery method ($180^\circ - t - 90^\circ$, **Figure 8(a)**), and T_2 measurements are based on variations in a spin–echo sequence such as the Carr–Purcell–Meiboom–Gill (CPMG) sequence ($90^\circ - (t/2 - 180^\circ - t/2)_m$, **Figure 8(b)**). Relaxation measurements are typically done on ^{13}C or ^{15}N of CH_n or NH_n signals as these groups exhibit well-defined relaxation from modulation of the local magnetic field from motion of directly attached protons. However, direct measurement of T_n for protein samples is hampered by insufficient resolution in 1D NMR spectra and poor sensitivity for detection of ^{13}C and ^{15}N nuclei with low gyromagnetic ratio (γ).

Although variations in the ^{15}N spin relaxation experiments have been described, the experiments more or less follow the same principles as in the heteronuclear 3D NMR experiments described above. In relaxation experiments, the magnetization can be transferred from ^1H to its directly attached ^{15}N or ^{13}C , the appropriate relaxation T_n sequence in **Figure 8** can be embedded in a suitable 2D or 3D NMR experiment where the magnetization resides on the nucleus whose relaxation characteristics are to be measured, and finally the magnetization is transferred back to ^1H for detection, to take advantage of the greater sensitivity for detection of ^1H compared to ^{15}N or ^{13}C . Each ^1H – ^{15}N pair in the protein gives rise to a unique cross-peak in the series of 2D or 3D spectra, with an intensity depending on the relevant relaxation equation on the left side of **Figure 8**, where t is the variable relaxation delay and T_n is either T_1 or T_2 . A series of experiments are run with variable t delays, and T_n is measured by fitting the cross-peak intensity variations to the relevant function of t .

Most of the relaxation experiments to probe backbone dynamics are based on ^{15}N relaxation, but experiments based on carbonyl carbon ($^{13}\text{C}'$) are also reported. T_1 relaxation experiments can also be used to probe the side-chain dynamics. The information about the fast motions contained in relaxation experiments can be interpreted in terms of two model-independent quantities: a generalized order parameter, S , which is a measure of the spatial restriction of the motion, and an effective correlation time, τ_e , which is a measure of the rate of motion (time-scale). Model-based interpretations, which correlate the data from the relaxation of both the ^{15}N and $^{13}\text{C}'$ nuclei, as they are part of the same backbone, are also possible.

Side-chain dynamics can also be investigated by using the data from deuterium (^2H) relaxation. For such an experiment, the protein needs to be uniformly labeled with ^{13}C and partially labeled with ^2H (or D). If a partially deuterated methyl group, that is $^{13}\text{CH}_2\text{D}$, is considered in

Figure 8 Graphic illustration of NMR signal components: (top) longitudinal (M_z) component in response to a $180^\circ - t - 90^\circ - T_1$ pulse sequence, and (bottom) transverse (M_{xy}) component in response to a $90^\circ - t/2 - 180^\circ - t/2 - T_2$ pulse sequence. These elements can be incorporated into standard 2D and 3D NMR experiments to resolve local structure dynamics in complex molecules.

the relaxation experiment, the magnetization is transferred from ^1H to ^{13}C , and then from ^{13}C to ^2H ; ^2H is allowed to relax during a variable time period t , and the magnetization is then transferred back through ^{13}C to ^1H for detection. The intensities of the ^{13}C - ^1H cross-peaks in the spectrum obtained this way are scaled by the ^2H relaxation.

The experiments to study micro- to millisecond timescale motions are based on the CPMG relaxation dispersion sequence, which in turn, is a modification of Hahn spin-echo experiment (shown in **Figure 8(b)**). The CPMG sequence was developed to measure exact T_2 relaxation by eliminating the effect of magnetic field inhomogeneity on signal decay in relaxation measurements.

If a protein can exist in two different conformational states A and B, and both the states are significantly populated, the NMR spectrum will be influenced by the population of the states and the exchange rate (R_{ex}). If $R_{\text{ex}} \ll \Delta\nu$ (where $\Delta\nu$ is chemical shift difference between the resonances of a nucleus in the A and B forms of the protein), two distinct peaks, one for each component/form of the protein, will be observed in the NMR spectrum. If $R_{\text{ex}} \gg \Delta\nu$, then rapid exchange of the protein

between the two conformational states will cause significant broadening of the peaks. In the latter case, if there is a significant difference between the populations of the two states, then only the peak from the most populated state will be observed and information about the exchange process cannot be obtained. This type of fast exchange process can be treated with the CPMG dispersion sequence, which can be written as $90^\circ x - (\tau - 180^\circ - \tau)_n - \text{detect}$, where the $(\tau - 180^\circ - \tau)$ component of the Hahn spin-echo sequence is repeated n times. In the CPMG sequence, a variable number of refocusing pulses are applied during a fixed time interval, and if the pulsing rate is fast enough, the effect of interconversion between the conformational states is reduced and sharp peaks are obtained. Although the CPMG sequence has been known for many years, application of the sequence to the study of protein dynamics waited for the inception of high-resolution nD NMR spectroscopy, which enabled scientists to resolve ^1H - ^{13}C or ^1H - ^{15}N cross-peaks from different sites of proteins, thereby permitting measurement of the relaxation-dependent intensity variations of these resolved cross-peaks.

Many of the amide protons are highly labile and undergo exchange with solvent molecules. The measurement of amide proton exchange with solvent molecules provides useful information about global stability and the dynamics of local structural fluctuations of proteins. Fast exchange rates, which fall within the timescale of 5–500 ms, can be studied by following the exchange of amide protons with water molecules, whereas slow exchanges that take minutes to days can be studied by following exchange of amide proton with deuterium of D₂O by dissolving protein in D₂O. In both cases, the diminishing signal intensity of the amide proton is followed.

nD NMR of Nucleic Acids

Like proteins, the structure and dynamics of nucleic acids (RNA and DNA) can also be studied with nD NMR spectroscopy. Nearly 50% of the nucleic acid structures reported so far were determined by NMR spectroscopy. The structure determination of RNA and DNA by NMR spectroscopy is limited by molecular weight. High-resolution structure characterization is possible for RNA/DNA with approximately 50 bases, whereas information with intermediate resolutions can be obtained from structures with 100 bases. Study of nucleic acids by NMR requires that they be isotopically labeled with ¹³C and ¹⁵N. Both biochemical and chemical methods can be used to achieve labeling. The choice of chemical methods is often limited by the difficulty in synthesis and the expense of the required ¹³C- and ¹⁵N-labeled precursors; RNAs and DNAs are most often labeled by biochemical methods.

The structures of nucleobases and sugars and their nomenclature are depicted in **Figure 9**. Nucleotides are the structural units of RNA and DNA. They are made of a nitrogenous base, a pentose sugar, and a phosphate group. Five nucleobases, adenine (A), thymine (T), cytosine (C), guanine (G), and uracil (U), are common in RNA. A, C, and G bases are common in both DNA and RNA, whereas T is found only in DNA and is replaced by U in RNA. In addition to bases, RNA contains the sugar ribose, whereas DNA contains deoxyribose, which lacks an –OH group in the 2' position. The bases are linked to the sugar through glycosidic bonds in which a nitrogen of the base, N1 and N9 in case of pyrimidines and purines, respectively, is linked to the C1' carbon of the sugar. The phosphate group links the 3' end of one sugar unit (*i*) with the 5' end of the next sugar unit (*i* + 1). In the primary structure of DNA and RNA, the nucleotides are linked through the 5' and 3' positions of the sugar group and form the DNA and RNA strands. One end of the strand has a free 5' end and the other end has a free 3' end, which gives the polarity of the DNA and RNA. Five torsion angles can be identified along the

sugar–phosphate backbone and are labeled in **Figure 9** as α , β , γ , δ , ϵ , and ζ , whereas the glycosidic torsion angle is named as χ .

The secondary structure of DNA consists of a double-stranded B-type helix where the strands run in opposite direction and are held together by hydrogen bonds. RNA is single stranded and does not form a well-structured B-type helix, the formation of which is prevented by the presence of the –OH group in the 2' position of the ribose sugar. Nonetheless, it can form an A-type helix and is capable of forming base pairs. The turns of the single strand are capable of forming base pairs, giving rise to secondary structural motifs such as hairpins, loops, and bulges in RNA.

The complete resonance assignment of the nucleic acid can be accomplished in four different steps: (1) identification of the nucleobase spin systems (H^N, NH₂, H2, H5, H6, and H8); (2) identification of the protons of the sugar (H1', H2', H3', H4', H5', and H5'') and complete assignments of the sugar spin systems; (3) identification of the connection between the sugar ring and the nucleobase; and (4) establishment of sequential links between the nucleotide spin systems.

To accomplish these steps, extensive use is made of 2D NOESY, ¹H–¹³C 2D HSQC, and ¹H–¹⁵N 2D HSQC experiments. Significant supplementary data for structure determination are obtained from 3D HHN NOESY-HSQC, 3D HHC NOESY-HSQC, and ¹H/¹³C/³¹P and ¹H/¹³C/¹⁵N triple-resonance 3D experiments (and their truncated 2D counterparts) analogous to those devised for protein structures. Since nD NMR spectroscopy is the subject of this article, these experiments will be the focus in this discussion.

The acronyms for some of the triple-resonance experiments used in nucleic acid structure determination are listed in the lower right part of **Figure 9**, along with a box with specific graphic codes to the left of the acronym. The corresponding structure features that are identified by each experiment are graphically highlighted on the purine and pyrimidine base structures in **Figure 9**. The nucleobase aromatic protons (H5 and H6 in the pyrimidines) are assigned based on NOE contacts between aromatic protons of the pyrimidine bases. H–H homonuclear correlations are not useful for identifying the protons within a purine base because of the large internuclear separation; for this purpose, a variety of H/C/N triple-resonance experiments is used, as illustrated in **Figure 9**. One of the major difference between experiments used in RNA/DNA studies and their protein counterparts is in the use of CC-TOCSY and CN-TOCSY transfers as opposed to INEPT-type transfers commonly used in protein structure studies. In a typical pulse sequence, the magnetization transfer steps usually starts from an imino or amino proton; this proton magnetization is transferred to the attached nitrogen atom by

Figure 9 Structure components of RNA showing typical purine and pyrimidine bases (top half) and how they are joined to the sugar-phosphate backbone. Acronyms for some of the typical nD NMR experiments used in RNA and DNA structure determination are shown in the lower right. The coded boxes next to these acronyms appear on the structures, to identify those structure features identified by each of the nD NMR experiments.

using an INEPT-based sequence; magnetization is then transferred to the attached carbon atoms via NC-TOCSY. The carbon atoms are then correlated through the CC-TOCSY transfer steps.

The sugar protons can be assigned by using the NOE correlation of sugar protons to the aromatic protons of the nucleobases. Aromatic protons typically show NOE correlations to the H1' proton of its own sugar and to the sugar of the preceding nucleotide in the 5' direction. The protons are identified by a sequential walk between NOE cross-peaks of different nucleotides. The starting point for such a sequential walk is either the strong NOE cross-peak between adenine H2 and H1' of the ribose ring or the NOE cross-peak of 5' and 3' nucleotides. The protons of the terminal nucleotides are shifted because of the missing phosphate group that facilitates the identification of their NOE cross-peaks. The intra- and internucleotide

NOE contacts have strong-to-weak correlations depending on their spatial distances that largely affect their cross-peak intensities. NOE experiments with different mixing times are also very helpful in identifying the different NOE contacts as cross-peaks between protons with large internuclear distances tend to appear at longer mixing times.

The correlation of the nucleobase N9 in purines and N1 in pyrimidines, with the H1' proton of its sugar, is obtained from the HCN triple-resonance experiment using ¹³C- and ¹⁵N-labeled RNA. This type of experiment also gives the correlation between H6-N1 of the pyrimidines and between H8-N9 and H8-N7 of the purines. The N1 and N9 ¹⁵N resonances are observed in the 145–155 and 170–175 ppm chemical shift regions, respectively, and can also be assigned from the HCN spectrum. As with the protein 3D sequence, this is an

INEPT-based out-and-back experiment where the magnetization transfer steps start either from the H1' proton and are then transferred to N1 or N9 via the C1' carbon, or from the H6/H8 protons and transferred to N1/N9/N7 via C6/C8 carbons. A modified version of the HCN experiment is the HCNCH experiment, where the HCN sequence is extended to relay magnetization via C6/C8 to H6/H8.

The assignment of the spin systems of the nucleobases is completed through the identification of the resonances of the heteroatoms that are attached to the nucleobase protons. This is accomplished by applying the standard ^1H - ^{13}C and ^1H - ^{15}N HSQC experiments. These HSQC experiments help to identify N7 and N9 of guanine and N1 and N3 of adenine. A 2D H(N)CO experiment utilizes the correlations between imino H3 protons and the C2/C4 atoms of uracil and thymine. The quarternary carbon atoms, C2 of cytosine and C4 of guanine, are assigned by using the HCNC experiment, where the magnetization transfer involves either $\text{H1}' \rightarrow \text{C1}' \rightarrow \text{N1}/\text{N9} \rightarrow \text{C2}/\text{C4}$ or $\text{H6}/\text{H8} \rightarrow \text{C6}/\text{C8} \rightarrow \text{N1}/\text{N9} \rightarrow \text{C2}/\text{C4}$ atoms. A modified HNCOCOA experiment is used to assign the quaternary C5 carbon atom in guanine.

All the resonance assignments of the sugar moieties can be obtained by applying a single 3D HCC-TOCSY-CCH-E.COSY experiment. This experiment is based on the initial frequency labeling of the H1' proton resonances (f_1 dimension), whose assignments were obtained from the sequential NOE walk. This experiment correlates the ^1H and ^{13}C chemical shifts of atoms within each sugar ring system by two sequential coherence transfer steps, an ^1H - ^{13}C INEPT transfer (selective for H1') followed by a CC-TOCSY, which utilizes the large $^1\text{J}_{\text{CH}}$ and $^1\text{J}_{\text{CC}}$ scalar couplings. After frequency labeling the sugar ring carbons (usually only C1', C2', and C3'), magnetization is transferred back to the sugar ring protons (H1', H2', H3', and H4'). In this 3D experiment, $\text{C}n'/\text{H}(n+1)'$ -type cross-peaks (where $n=1-4$) are obtained in a frequency plane corresponding to the chemical shift of the H1' proton. Vicinal J_{HH} couplings can also be extracted from the f_3 dimension, yielding information about the sugar ring conformations.

Sequential assignment of the sugar systems is obtained from an HCP experiment, which involves out-and-back INEPT transfer steps. This experiment correlates the $\text{H3}'/\text{C3}'i$ and $\text{H4}'/\text{C4}'i$ resonances with P_{i+1} on the 3' side and the $\text{H5}'/\text{H5}''/\text{C5}'i$ and $\text{H4}'/\text{C4}'i$ resonances with P_i on the 5' side of the phosphodiester backbone.

The hydrogen bonds between base pairs are formed by the imino and amino protons interacting with carbonyl and tertiary N atoms. AU in RNA (AT in DNA) and GC are known as the Watson-Crick base pairs and normally occur in the nucleic acids, but other types of base pairs can also be formed. The chemical shift of the imino proton resonances depends on the chemical environment, base stacking,

ring effects, and presence/absence of solvent molecules. Base-pairing patterns give important information about the secondary structure of the nucleic acids. The base-pairing pattern is obtained from the sequential assignment of imino proton resonances obtained from homonuclear NOE experiments. Intercatenary $^2\text{J}_{\text{NN}}$ couplings mediated by N-H-N interbase hydrogen-bonding interactions are also often resolved in ^{15}N chemical shift-encoded nD NMR experiments, and can serve as an additional means of identifying base-pairing interactions.

The RNA dynamics can also be investigated by using RDC information of atoms in the sugar moiety. Recently, a 3D NMR experiment was proposed, which can be used to simultaneously obtain five dipolar couplings from a single experiment. The couplings are extracted from the $\text{H1}'\text{-C1}'\text{-C2}'\text{-H2}'$ spin systems. This experiment involves out-and-back INEPT transfer steps and transfers magnetization from H1' to C2' via $\text{H1}'\text{-C1}'$ multiple quantum coherence, which then evolves as single quantum coherence during a constant-time evolution period t_1 , and is transferred back to C1', which evolves during a constant-time evolution period t_2 and then to H1' for detection. Using the conventional practice of naming the 3D experiments, this experiment would be named as the H1C1C2 experiment. Proton decoupling is not applied so that the ^{13}C - ^1H doublet components in the f_1 and f_2 dimensions are split by $^1\text{J}_{\text{C2}'\text{H2}'} + ^1\text{DC2}'\text{H2}'$ and $^1\text{J}_{\text{C1}'\text{H1}'} + ^1\text{DC1}'\text{H1}'$, respectively. The elimination of ^1H pulses during the evolution of t_1 and t_2 evolution period ensures the displacement of the two $\text{C1}'\text{-H1}'$ doublets and $\text{C2}'\text{-H2}'$ doublets relative to one another by $^2\text{J}_{\text{C1}'\text{H2}'} + ^2\text{DC1}'\text{H2}'$ and $^2\text{J}_{\text{C2}'\text{H1}'} + ^2\text{DC2}'\text{H1}'$, respectively. The fifth coupling $^3\text{J}_{\text{H1}'\text{H2}'} + ^2\text{DH1}'\text{H2}'$ is obtained from the f_3 displacement between the downfield and upfield $\text{C2}'\text{-H2}'$ doublets. The couplings are measured in the isotropic state and in the presence of liquid crystalline Pfl (anisotropic state) to obtain the five dipolar couplings for each nucleotide.

3D NMR of Synthetic Macromolecules

The biological 3D NMR methods have also been adapted to study the structures of complex synthetic macromolecules such as dendrimers, organometallics, and co- and terpolymers. Two strategies were used depending on the nature of the structures studied. A more generalized version of the $^1\text{H}/^{13}\text{C}/^{31}\text{P}$ triple-resonance experiment, where the third nucleus ^{31}P is replaced by X, where X can be any NMR-active nucleus that produces resolvable J_{CX} coupling. Examples have been published where H-C-X ($\text{X} = ^{119}\text{Sn}$, ^{31}P , ^{29}Si , ^{19}F , and ^6Li) structure fragments were identified in complex macromolecules or complex mixtures of small molecules. In some cases, $^1\text{J}_{\text{CX}}$, $^2\text{J}_{\text{CX}}$, $^3\text{J}_{\text{CX}}$, and sometimes even $^4\text{J}_{\text{CX}}$, couplings are resolved and fall in well-defined ranges so that a series of 3D experiments in which $^n\text{J}_{\text{CX}}$ INEPT polarization transfer

delays could be optimized to produce spectra in which $\underline{\text{H-C-X}}$, $\underline{\text{H-C-C-X}}$, $\underline{\text{H-C-C-C-X}}$, and even $\underline{\text{H-C-C-C-C-X}}$ structure fragments could be identified. Taken together, the experiments provide a complete picture of the structure around the X heteronucleus. In polymers such as polycarbosilanes, where an X unit is present in each monomer unit, it was possible to identify each unique monomer unit (in its monomer or stereo sequence) and its connectivity to adjoining monomer units.

Similarly, use of a more generalized version of the HCACO protein NMR experiment has been described, where the protein CA and CO pulses are replaced with pulses applied to any two coupled carbons C_A and C_X (where these carbons form an AX spin system in their ^{13}C spectrum) with $^1\text{J}_{\text{CACX}}$, and with ^{13}C chemical shifts resolved from each other. The majority of applications involve studying the structures of ^{13}C -labeled terpolymers of ethylene, carbon monoxide, and an acrylate monomer, labeled with either ^{13}C -carbon monoxide or ^{13}C -acrylate. Resonances from the environments of each unique acrylate (or $>\text{C}=\text{O}$) unit could be resolved in HCACX-3D NMR spectra. The ^1H resonances of adjoining monomer units could be detected and assigned by addition of an HH-TOCSY spin-locking sequence immediately before ^1H detection to form an HCACX-HH-TOCSY 3D NMR experiment. Together, the two 3D NMR experiments provided an enormous amount of detailed information on the structures of very complex polymers. The methodology was applied to structures in which the CA and CX chemical shifts differed by as little as 35 ppm on a 750 MHz spectrometer.

Experimental Aspects of nD NMR

Methods for Collection of 3D NMR Data

Until recently, 3D NMR data were collected by the simple extension of 2D NMR methods to add an additional dimension. Several drawbacks are associated with this methodology: (1) the addition of an evolution time-mixing period sequence results in signal reduction from relaxation processes and imperfect pulse sequence elements; (2) simple extension of 2D NMR methods to a third dimension requires the collection of m -2D NMR data sets so that the experiment time is increased m -fold; and (3) the data set size is increased at least by m -fold.

The sensitivity issue is rarely a problem, especially with NMR measurements on isotopically labeled molecules. Very often, sufficient signal-to-noise ratio is achieved early in the experiment, and signal averaging must proceed to sample a sufficient number of points in each of the evolution time dimensions to achieve the needed spectral resolution. In practice, to shorten experiment time, a minimal number of t_1 and t_2 increments

are sampled; 8–32 points (evolution time increments) in each dimension is not unusual. To make up for the small number of sampled points, narrow spectral windows are often used; it is not unusual for peaks to be aliased three and four times (see data in **Figure 5** where eight separate C–H correlations are observed in a single ^{15}N chemical shift plane). Despite extensive aliasing, resolution of peaks is not usually a problem. Liberal use of mathematical data extension techniques such as linear prediction or maximum entropy methods helps to improve the digital resolution in the final spectrum.

Methods for Collection of nD NMR Data

When nD experiments are extended beyond $n=3$, application of the simplest short cuts, used in 2D NMR and mentioned earlier in text for 3D NMR, are not adequate. Sparse sampling methods and methods based on non-Fourier transform processing become essential to shorten 4D NMR experiments to reasonable data collection times. The filter diagonalization method (FDM) is among the methods used to shorten data collection times. Here very few points (two to four increments) in each of the evolution time dimensions are sampled and the data are transformed as a true nD data set, as opposed to treating each time dimension independently in the transform from time to frequency domain. Under these conditions, the large number of points sampled in the directly detected dimension, collected at very little cost of experiment time, contributes to the digital resolution in the indirectly detected dimensions.

As an alternative, maximum entropy methods (MEM) can be combined with sparse data point sampling in the indirectly detected dimension. Rather than simply extending a truncated free induction decay (FID), a fraction of the points in the indirectly detected dimension are sampled over an extended time period. Because the signal is more intense at short values of the evolution times, the point samplings are at semirandom intervals with a higher weighting of sampled points for short values of the evolution time (where the signal is more intense) and more sparse sampling at long values of the evolution time. The nature of MEM is such that processing does not require sequential data points so that randomly sampled FIDs in the evolution times can be transformed from the time to the frequency domain.

Two methods of shortening nD NMR experiments that are not relevant to 2D NMR techniques are the GFT-NMR and projection reconstruction techniques. In both methods, two or more evolution times are simultaneously incremented. A systematic nomenclature has been devised to describe GFT techniques. The nomenclature begins with the base nomenclature discussed above (outlined in **Figure 6**), which uses letters to describe the coherence transfer path in nD NMR

Figure 10 GFT-NMR data: (A1–A15) Fourier transformed data; (A1–A8) $[f_1(^{15}\text{N}, ^{13}\text{C}', ^{13}\text{C}^\alpha, ^1\text{H}^\alpha)/f_2(^1\text{H}^\alpha)]$; (A9–A12) $[f_1(^{15}\text{N}, ^{13}\text{C}', ^{13}\text{C}^\alpha)/f_2(^1\text{H}^\alpha)]$; (A13–A14) $[f_1(^{15}\text{N}, ^{13}\text{C}')/f_2(^1\text{H}^\alpha)]$; (A15) $[f_1(^{15}\text{N})/f_2(^1\text{H}^\alpha)]$; and (B1–B15) resulting spectra from linear combinations of A1–A15 based on G-matrix manipulation so that each chemical shift component is identified. Reproduced from Seho K and Szyperski T (2003) *Journal of the American Chemical Society* 125: 1385–1393.

experiments for protein structure determination. The dimensionality of the experiment is described by $(n, n - k)$ D NMR, where n is the dimensionality of the final spectrum and $k + 1$ is the number of simultaneously incremented/sampled evolution times. A $(5, 2)$ D HACACONHN experiment will ultimately yield a 5D

NMR spectrum correlating $^1\text{H}_\alpha/^{13}\text{C}_\alpha/^{13}\text{C}=\text{O}/\text{amide } ^{15}\text{N}/\text{amide } ^1\text{H}$ resonances. It is run as a 2D experiment in which $k + 1 = 4$ dimensions are simultaneously incremented. The evolution times that are simultaneously incremented (t_1 , t_2 , t_3 , and t_4) correspond to the underlined letters in the pulse sequence name – in this case,

the evolution times that encode $^1\text{H}_\alpha/^{13}\text{C}_\alpha/^{13}\text{C}=\text{O}/$ amide ^{15}N chemical shifts. A simple Fourier transform of the resulting data in this case is a 2D NMR spectrum in which the chemical shift of the base nucleus is modulated by the remaining three chemical shifts, producing a series of doublet splittings, as illustrated by the top half of **Figure 10** (A1–A8). If linear combinations of the resulting data are taken (based on a calculated G-matrix), spectra will be obtained, with all five chemical shifts resolved. In spectra from complex proteins, there are usually numerous cross-peaks at the shifts of the base nuclei. To assign these, it becomes necessary to also acquire a series of base spectra where t_1 , t_2 , and t_3 are simultaneously incremented (**Figure 10**, A9–A12), t_1 and t_2 are simultaneously incremented (**Figure 10**, A13–A14), and t_1 alone is incremented (**Figure 10**, A15). Linear combinations of the resulting data are taken (based on a calculated G-matrix) to produce a set of spectra with all five chemical shifts resolved as illustrated in **Figure 10** (B1–B15).

Projection reconstruction methods are related to the GFT technique in that a series of spectra are acquired in which multiple evolution times are systematically incremented to produce a series of 1D spectra skewed through frequency space. The resulting 1D spectra represent the projections of the cross-peaks from the nD spectrum onto the 1D axes. The nD spectrum is reconstructed by back projection of the acquired 1D spectrum into nD space. The projection reconstruction method for the simplest case of a 3D NMR spectrum with two cross-peaks is illustrated in **Figure 11**. Cross-peak positions in the f_3 dimension are determined by data sampling in t_3 (acquisition time dimension), and there is no significant time advantage from sparse sampling of points in this dimension. If a spectrum is acquired by holding $t_2=0$ and incrementing t_1 , then the 1D (f_1) spectrum along the f_1 axis in **Figure 11(a)** is obtained and the family of peaks in the f_1f_2 plane that serve as solutions consists of two parallel sets of peaks in the f_1f_2 dimension. If a second spectrum is acquired by holding $t_1=0$ and incrementing t_2 , then the 1D (f_2) spectrum along the f_2 axis in **Figure 11(b)** is obtained and the family of solutions that satisfies the constraints imposed by the f_1 and f_2 spectra consists of four cross-peaks in the f_1f_2 dimension at the intersections of the frequencies determined by back projection of the f_1 and f_2 spectra. In **Figure 11(c)**, t_1 and t_2 are incremented simultaneously to produce a spectrum skewed across the spectrum; the final f_1f_2 plane from the 3D spectrum results from the family of solutions that produces all three 1D projections and, in this case, contains only two peaks.

In projection reconstruction methods, the required number of 1D traces depends on the number of cross-peaks expected in the nD spectrum, the method of calculating the back projection (reconstruction algorithm),

Figure 11 Schematic diagram illustrating the back-projection-reconstruction of the f_1/f_2 domains in a 3D spectrum: (a) the back projection of data from one series of experiments performed with t_2 fixed and t_1 incremented produces a family of solutions with possible peaks along two ridges; (b) the back projection of the data from a second series of experiments performed with t_1 fixed and t_2 incremented reduces the family of solutions to four peaks; and (c) the back projection of the data from a third series of experiments performed by simultaneously incrementing t_1 and t_2 produces the final spectral solution. Full resolution is obtained in the final spectrum, with sampling of far fewer points than if all points in the t_1 and t_2 dimensions were systematically sampled as in a standard 3D FT NMR experiment.

and whether quantitative peak volumes are desired. There is a variety of reconstruction algorithms that can be used, and the choice of algorithm depends on the inherent signal-to-noise ratio in the spectrum.

Summary

Advancements and enthusiasm in the NMR field show no signs of waning after more than five decades of rapid advancements. Computer hardware and data processing methodology continue to keep pace with increasing demands to handle larger and larger data sets. Revolutionary NMR technology continues to be developed so that elaborate methodology can be applied to problems involving smaller quantities of material with increasingly complicated structures.

Introduction

While near-infrared spectroscopy was for many years a sleeping giant, the diversity of instrumentation available today attests to its new-found and widespread acceptance as an analytical method. The aim of this article is to outline the measurement principles for each of the various types of instruments that are commercially available, and to outline the strengths of each. Because analysis is by far the most common application, we also include accounts of specialized measurement techniques that have emerged for on-line, *in situ*, and remote spectral measurements, as well as briefly outlining dedicated analysers founded upon near-infrared technology.

The near-infrared (near-IR) falls between the visible and mid-infrared regions, with corresponding vibrational frequencies in the terahertz range (**Figure 1**). It has become customary to report near-IR absorption positions in units of wavelength, either micrometres or nanometres, although it is becoming more common to see positions measured in wavenumbers (cm^{-1}). Simply the inverse of the wavelength (in cm), the wavenumber scale has become standard for mid-infrared spectroscopy and is becoming more commonly used for near-IR work. The advantages most often cited are that the scale is linear in energy and that it provides values of a convenient order of magnitude, particularly in the mid-infrared.

It seems odd at first glance that the near-IR region remained largely an afterthought for many years, given the relatively long and productive histories of both UV-visible and mid-infrared spectroscopy. However, the weak bands in the intervening near-IR region were long viewed as being superfluous; with broad, weak absorptions corresponding almost exclusively to overtones and combinations of vibrational modes, it was (and still is)

Figure 1 The near-infrared lies between the visible and mid-infrared regions, ranging from 780 to 2500 nm.

generally considered that the structural information latent in the spectra is far more readily available from the mid-infrared spectra.

Times change. The 1980s and 1990s witnessed revolutionary growth in the use of near-IR spectroscopy as an *analytical* technique. Near-IR spectrometers may now be found in applications ranging from agriculture to food processing and pharmaceuticals. Estimated at \$4 500 000 in 1977, near-IR instrumentation revenues exceeded the \$100 000 000 mark in 1997 and continue to grow at a compound rate of 20% annually. This demand has spurred the development of a variety of near-IR spectrometers ranging from dedicated analysers to research-grade systems of enormous versatility. Remote measurements may be carried out in conjunction with fibre optics, and, from a vantage point aboard the Hubble telescope, even more distant measurements are being carried out as the near-IR camera and multi-object spectrometer 'NICMOS' yields a new vision of the universe. Application of the same spectroscopic-imaging technology is yielding new insights here on Earth, and the future will be eventful ones as this technique begins to live up to its potential.

Instrumentation: An Overview

Historical Development

In 1800, William Herschel assembled a spectrometer in which the Sun served as the source of radiation, a prism as the dispersing element, and a thermometer as the detector. Having first measured the distribution of radiant heat across the visible region, he then took the unprecedented step of moving the thermometer to a position beyond the red end of the spectrum. To his surprise, the thermometer registered not only heat, but a higher temperature than that found in the visible region. This signalled the discovery of a 'non-visible spectrum', and coincidentally of the first near-IR spectrometer.

The idea of a spectrometer dedicated to near-IR spectroscopy is relatively recent, and the early commercial near-IR instruments were simply UV-visible (or mid-infrared) spectrometers fitted with an additional detector and occasionally a second grating blazed for the near-IR. This equipment provided the basis for the pioneering work of Kermit Whetzel and Wilbur Kaye, who were largely responsible for laying the foundation of analytical near-IR spectroscopy. The development of modern near-IR instrumentation was spurred by research at the US Department of Agriculture; Karl Norris discovered that no commercial spectrometer of the time could provide diffuse reflectance measurements of the quality he required, and developed his own computerized near-IR spectrometer for meat analysis. The original aim of this work was to develop a convenient means to

monitor the water content of agricultural products. The research was complicated by the observation that components other than water contributed to the absorption profiles; however, this observation was quickly turned to advantage when it was found that protein could be quantified accurately from the near-IR spectrum of wheat. Under the direction of Phil Williams, the near-IR method was adopted by the Canadian Grain Commission to replace routine Kjeldahl testing. It worked, and spurred the widespread adoption of near-IR spectroscopy as an analytical method, and with it the birth of dedicated near-IR instrumentation.

What Is a Near-IR Spectrometer?

It is easy to find a pair of near-IR spectrometers that would not be recognizable as belonging to the same species even placed side by side. This diversity has arisen largely as a result of the tremendous variety of applications, with each unique application satisfied by a unique set of design and performance characteristics.

Some of the spectral criteria that characterize and differentiate near-IR spectrometers are wavelength accuracy and precision; photometric accuracy, precision, and linearity; signal-to-noise; and resolution (or spectral bandwidth). Among these, the attributes that are most important for analytical work are wavelength precision, photometric precision, and signal-to-noise. While the last may occasionally be sacrificed, it is generally the case that the signal-to-noise is the limiting factor governing the analytical accuracy; spectra are commonly measured with noise at single-digit micro-absorbance levels.

Practical considerations almost always play a role in choosing a near-IR spectrometer, reflecting specific demands that may be placed by a specific application. Among these considerations are size and/or portability; speed; susceptibility to extreme (e.g. industrial) environments; cost; measurement type; and flexibility (e.g. can the spectrometer be used only for transmittance measurements, or are reflectance and/or fibre optic measurements feasible?). Manufacturers consider all of these factors. For example, it is common to find commercial instrumentation housed in enclosures that are ruggedized to meet specific industry standards (National Electrical Manufacturers Association – NEMA).

For convenience, the spectrometers discussed in this article have been divided into the six design categories and variations illustrated in **Figure 2**. The instrumentation will be discussed after first introducing two essential components, the source and the detector.

Near-IR Sources

The most common broadband light source used for near-IR spectroscopy is the tungsten-halogen lamp, typically

Near-infrared instrumentation

Figure 2 Near-infrared instrumentation.

powered by a stabilized DC power supply. This source provides high energy throughout the near-IR, and has a long life with the halogen acting as a scavenger to deposit tungsten vapour back onto the filament.

Detectors

No single detector covers the entire 780–2500 nm near-IR range. The detectors most commonly used for near-IR spectroscopy are lead sulfide (or lead selenide) photoconductors and silicon photodiodes, with PbS(Se) covering the region 1100 to 2500 nm and Si the visible to 1100 nm range. A huge advantage of these detectors is that both provide good signal-to-noise operation at room temperature. **Figure 3** illustrates the specific detectivities (D^*) as a function of wavelength for PbS, PbSe, Si, and other detectors. As illustrated, both PbS and PbSe become more sensitive at lower temperatures, and some spectrometer manufacturers do capitalize on this. The alternative detector most commonly used at wavelengths longer than 1100 nm is indium gallium arsenide (InGaAs), which extends to 1800 nm with a substantially better D^* than either PbS or PbSe. At the expense of some sensitivity, the range of the InGaAs detector may be extended still further to 2200 nm, or even 2600 nm. Thermoelectric cooling is commonly used to increase D^* , but this improvement comes at the expense of long-wavelength response (**Figure 3**).

Fixed-grating spectrometers require a linear detector array for the simultaneous detection of the spectral elements dispersed along a line, and imaging applications require a two-dimensional detector array for spatial resolution. While both types of array are available for all of the detector materials included in **Figure 3**, those most commonly used are silicon, InSb and InGaAs.

Near-IR Instrumentation

The following sections are intended to illustrate the measurement principles for commercial near-IR spectrometers and to provide an understanding of the strengths inherent in each design. Because near-IR spectroscopy and chemical analysis are inextricably linked, particular emphasis is placed on features relevant to this application.

Grating Instruments

Scanning-grating spectrometers

In this category, it is important to distinguish spectrometers that are designed explicitly for quantitative analytical applications from those that are not. Several manufacturers offer conventional scanning single-monochromator spectrometers that extend from the ultraviolet region through the visible and near-IR. The main attraction of these instruments is the wide-wavelength coverage. A second monochromator may be included, which reduces the stray light and increases spectral resolution; these instruments have extraordinary photometric range, with linear response to 6 absorbance units and beyond. For analytical work however, these UV-visible near-IR spectrometers do not match the performance – in particular the combination of speed and signal-to-noise – that dedicated near-IR instrumentation provides.

On the other hand, commercial rapid-scanning monochromators that incorporate both PbS and Si detectors are capable of scanning the range 400–2500 nm in about 1 s. Typically 30 to 60 scans are co-added to provide a spectrum with very low noise levels (typically less than 30 microabsorbance units) within a minute or so. There are a

Figure 3 Specific detectivities and wavelength ranges for near-infrared detectors.

wide variety of applications that require this combination of speed and accuracy, and the relatively high cost of these instruments is fully justified for these applications. These spectrometers are also found in research laboratories. The role of the 'high-end' research spectrometer is to test the feasibility of new analytical applications and, if successful, to provide a basis to judge how best to implement the method in the field. Is the full spectrum required, or will discrete wavelengths suffice? What spectral regions (and hence detectors) are essential? What is the minimum signal-to-noise that will still yield acceptable analytical results? It is often the case that the only way to answer these questions is to carry out a careful study using a full-range research-grade spectrometer.

Fixed-grating spectrometers

The near-IR spectrum may be obtained by using a grating spectrometer with no moving parts at all. Since the grating disperses the spectrum of the source along an axis, the spectrum may be measured by an array of detector elements spaced along that axis (**Figure 4**). The most common detectors are silicon photodiode (PDA) and charge coupled device (CCD) arrays, with thermoelectrically cooled InGaAs arrays available for operation above 1100 nm. One advantage of this design is that it may be miniaturized to the point where the spectrometer is truly portable; these 'mini spectrometers' typically accept light via a single strand fibre optic cable of

Figure 4 The fixed-grating array detector. The grating spreads the spectrum across the array of detector elements so that each element senses a different wavelength.

10–1000 μm diameter, with resolution of 0.5 to 10 nm depending on the choice of grating and slit. They are inexpensive enough that several configurations, optimized for various resolutions and spectral bandwidths, may be linked in parallel by running several fibres from the same source.

It is possible to combine the mechanical stability of fixed gratings with a single-element detector. One manufacturer provides a subtractive double-monochromator system with the wavelength scanned by displacement of movable intermediate slits. Using slits cut in

a rotating disk, this arrangement is capable of acquiring up to 1000 spectra per second. While the design was developed primarily for kinetic studies in the visible region, extension to the near IR is readily achieved.

Interference Filters and the Fabry–Perot Interferometer

A number of commercial instruments make use of a set of interference filters to send discrete bands of radiation successively through the sample. In their simplest form, these filters appear as illustrated in **Figure 5**. Flat plates coated with dielectric reflecting layers are placed in parallel. Incident light undergoes multiple reflections in the region between the two plates, and the transmitted components interfere constructively or destructively as a

Figure 5 The interference filter. The profile of the transmitted intensity I_t is an Airy function whose bandwidth is governed by the reflectivity of the dielectric-coated reflective layers.

function of (i) incident angle θ , (ii) gap thickness ' d ', (iii) refractive index of the material between the reflective plates, and (iv) wavelength ' λ '. If the light is incident normal to the surface of the filter, the transmission profile has a maximum centred at a wavelength $\lambda_{\max}$ equal to twice the gap thickness ' d ', with higher-order transmission maxima at $\lambda_{\max}/2$, $\lambda_{\max}/3$, $\lambda_{\max}/4$, etc. The desired order is selected using appropriate high-pass and low-pass filters.

Quite elaborate filters may be built upon this principle, with bandwidths ranging from 0.25 up to 10% of the centre wavelength. A typical instrument includes several filters mounted on a rotating filter wheel (**Figure 6**). The wheel may include a set of filters with bandpasses tailored to fit the requirements of a specific application or, if the instrument is to be used for a variety of applications, a set of filters to survey the near-IR region of interest.

Because of the angular dependence of the transmission profile, the peak transmitted wavelength may be fine-tuned by tilting the filter relative to the incident beam. In fact, this property has been capitalized on to scan small spectral regions using a single filter, and one commercial instrument used seven tilting filters of appropriate centre wavelengths to cover the 1400–2400 nm region. However with the advent of inexpensive holographic gratings, the tilting-filter instrument is no longer manufactured commercially.

The same interference principle may be applied to make a circularly variable filter. The cavity thickness, and hence the centre wavelength, varies systematically around the circumference of the filter. Rotating the disk in a position between the source and the detector scans the wavelengths. Similarly, the cavity thickness may vary systematically along a line to produce a linearly variable filter suitable for use with an array detector. While neither of these has found wide application for analytical

Figure 6 A filter-based instrument operating in reflectance mode. The sample is probed with the mirror in the 'sample' position, and the beam is directed to the internal surface of the integrating sphere to measure the background. Courtesy of Bran + Luebbe Analyzing Technologies Ltd.

work, both find niches in applications where a broad bandpass is not an issue.

The Fabry–Perot spectrometer is an interference filter in which the centre transmitted wavelength is scanned either by varying the gap between the parallel plates or by varying the refractive index of the medium separating them. Again, this design is not widely used for analytical work, primarily due to practical difficulties in manufacturing devices that work in first order across the near-IR region. Devices operating at higher order may have extraordinarily high resolution; however, the free spectral range is correspondingly narrow.

The optical path of the liquid-crystal tunable filter comprises a series of polarizers and liquid crystal elements whose birefringent properties are electronically controlled. These devices can select wavelengths ranging from the visible to 1100 nm, with a bandwidth as low as 5 nm. The wide, circular aperture makes it particularly attractive as a means to select wavelength regions for transmission to a near-IR camera.

The Michelson Interferometer

The Michelson interferometer does not measure the infrared spectrum directly. Rather, an ‘interferogram’ is measured, and converted to a single-beam spectrum via Fourier transformation. Because of the critical role of this transformation, the method is generally referred to as Fourier-transform infrared spectroscopy, or ‘FT-IR’. Instruments using this design have proven to be suitable for a number of near-IR applications.

The optical layout is illustrated in **Figure 7**. As the moving mirror is displaced, there is an increasing difference in the optical pathlength travelled by the two components incident on the detector. This results in interference between the two merging beams, and for a monochromatic source of wavelength λ_1 the resulting AC signal (a mirror is moving!) is a cosine wave. The Fourier transform of this interferogram is an infinitely narrow ‘band’ (delta function) at a position $1/\lambda_1$. (FT-IR spectra are typically reported in wavenumbers (cm^{-1}), the inverse of the wavelength (and, not coincidentally, the inverse of the unit of length measuring the optical-path-difference that defines the horizontal axis of the interferogram). The scale is linear in energy, and the resolution is a constant in these units.) For a polychromatic source, the ideal interferogram is a superposition of cosine waves, one for each ‘colour’ in the spectrum of the source; the Fourier transform converts this to the emission spectrum of the source. The absorption spectrum is acquired by placing a sample before the detector in the optical path, repeating the measurement and ratioing the two single-beam spectra.

Although they have long been the design of choice for mid-IR spectroscopy, FT-IR instruments have now

Figure 7 The Michelson interferometer. The beamsplitter splits light from the broadband source S into two components that travel separate paths to mirrors M1 and M2. The recombined beams incident on the detector D move progressively further and further out of phase as the moving mirror is scanned. The interferogram is a plot of the AC component of the detector signal vs the path difference.

become popular in analytical near-IR applications. This emergence is due in large part to improvements in the interferometer design and materials, resulting in modern instruments that are very stable both in the short and in the long term. Because the position of the moving mirror and the digitization interval are monitored very accurately by a parallel helium–neon laser interferometer, the FT-IR spectrometer is also characterized by superb wavelength (wavenumber) accuracy and precision.

The Michelson interferometer combines very good signal-to-noise with high spectral resolution. The resolution is governed by the maximum displacement of the moving mirror, and a resolution of 4 cm^{-1} or better is readily achieved. For comparison, a bandpass of 10 nm is typical for grating near-IR spectrometers; the relatively wide slit is preferred in order to transmit enough energy to quickly record spectra of good signal-to-noise. **Figure 8** graphically illustrates the resolution advantage of a Michelson interferometer operating at 4 cm^{-1} or even at 16 cm^{-1} nominal resolution. While the practical advantages of the higher resolution remain largely unexplored, there is little doubt that the enhanced ability to distinguish closely spaced absorptions will prove beneficial in some analytical applications.

Two final points specific to FT-IR spectrometers should be mentioned. First, the signal-to-noise ratio can often be improved by using an optical bandpass filter to isolate the spectral region of interest. Second, this approach is particularly well suited for measurements where the light flux on the detector is low, for example for measurements using fibre optics where the light-gathering efficiency may be quite poor.

Figure 8 Comparison of the resolution of an FT-IR (Michelson) spectrometer to that of a grating spectrometer. The solid lines represent the resolution of a grating spectrometer with a bandpass of 10 nm and the resolution (in nm) for an FT-IR spectrometer operating at a nominal resolution of either 4 cm^{-1} or 16 cm^{-1} (because noise levels rapidly increase for narrower slitwidths, a 10 nm bandpass is typical of analytical rapid-scanning grating spectrometers). For example, an FT-IR spectrometer operating at 4 cm^{-1} resolution has an effective bandpass of 2.5 nm at 2500 nm, falling to less than 0.5 nm at 800 nm.

Acousto-Optical Tunable Filters

If an acoustic wave is produced in a suitable crystal, the result is that the refractive index varies periodically across the crystal. Intuition would then suggest that the crystal might act as a grating with diffraction properties governed by the wavelength of the sound wave.

In fact the crystal does act as a monochromator, but the mechanism underlying this phenomenon is more complex than the simple diffraction grating analogy would indicate. In fact the process is governed by a phonon–photon scattering mechanism, the details of which lie beyond the scope of this article. The result, however, is that a tellurium oxide crystal with one or more piezoelectric transducers (PZTs) bonded to it acts as a monochromator (**Figure 9**). Wavelength selection is achieved by varying the driving frequency of the PZTs, and the intensity may also be varied by varying the driving power. The resolution is governed by the physical size of the crystal (or, more precisely, by the length of the path over which the light/crystal interaction takes place).

Two distinctive features of this design are the fact that it has no moving parts and that there is ‘random access’ to any pre-selected wavelength or set of wavelengths. Wavelength stability, precision, and accuracy are also very good, since the wavelength selection is controlled by the RF drive. But the most striking feature of the design is the speed of measurement.

Spectrometers Using Discrete-Wavelength Sources

Light-emitting diodes (LEDs) are available with centre wavelengths throughout the NIR range, and are used as

the basis of near-IR instruments with no moving parts. Because LEDs typically have bandwidths of 50 nm or larger, a small interference filter is required to select the desired centre wavelength and bandwidth. An appropriate set of filtered LEDs may then be assembled to span the wavelength range of interest, and the spectrum acquired by cycling through the set. Two advantages of this design are that the instrument can easily be miniaturized, and that the LED sources are stable for decades. Commercial instruments are in essence portable analysers that happen to be based upon near-IR spectroscopy, with built-in calibrations to give direct read-out of analyte levels.

Imaging Spectrometers

Every picture tells a story. This is as true in the near-IR as it is of the visible, and the combination of imagery and spectroscopy is a marriage with a short track record but enormous potential.

In its simplest form the measurement requires a near-IR camera, typically equipped with a two-dimensional silicon array detector, with some means to select wavelengths. Some of the advantages of spectroscopic imaging may be realized by simply using fixed bandpass filters to capture images at two or more discrete wavelengths; two judiciously chosen wavelengths often complement one another to provide information that is not available from either of the individual images.

The full potential of near-IR imaging spectroscopy is realized by replacing the fixed bandpass filters with a monochromator having a continuously variable bandpass. Several possibilities exist. The Fabry–Perot interferometer is suitable for scanning over small wavelength

Figure 9 Acousto-optical tunable filter. Courtesy of Brimrose Corporation.

Figure 10 Near-infrared spectroscopic imaging. A series of N images is acquired using a CCD-array camera, using optical filtering to step successively through the near infrared (800–1100 nm in this illustration). An N -point near-infrared spectrum may then be reconstructed for each pixel in the image. Courtesy of Jim Mansfield.

ranges at high resolution, and is used primarily for astronomical observations. Two elements most commonly used for imaging across wide spectral regions are the acousto-optic tunable filter and the liquid-crystal tunable filter. **Figure 10** illustrates the kind of data that can be measured using this type of arrangement; a series of images is acquired at discrete wavelengths, and a spectrum then constructed for each pixel by extracting the corresponding intensity value for each image in the series. The analogous experiment has been carried out using a Fourier-transform spectrometer, using an infrared microscope in combination with an InSb focal-plane array

detector. In that instance, an interferogram is collected at each pixel and transformed to yield the near-IR spectra.

Sampling Methods: From the Laboratory to On-line

Diffuse Reflectance

Analytical applications of near-IR spectroscopy can only succeed if the sample can be presented to the spectrometer in a reproducible fashion. This is simple enough for liquids, but less straightforward for solid, physically

Figure 11 Typical geometry used for diffuse-reflectance spectroscopy. The detectors may be the same materials, or two different materials (e.g. Si and PbS) for wider wavelength coverage.

inhomogeneous samples. The most common solution is to measure radiation that is diffusely reflected from the sample. **Figure 11** illustrates a typical configuration for this measurement, with two detector elements at 45° to the surface. Another way to collect the reflected radiation is to use an integrating sphere, as illustrated in **Figure 6**. In either event, the reflectance spectrum of a coarse, inhomogeneous sample is influenced to some degree by the surface terrain. This influence is typically minimized either by spinning the sample or translating the surface of the sample stepwise across the beam. It should be mentioned that the Michelson interferometer is not well suited for reflectance measurements of coarse moving samples. The moving sample modulates the intensity of the reflected light, giving rise to a noise component that superimposes on the interferogram. The result upon Fourier transformation is a noisy spectrum.

Fibre Optics, On-line and *In Situ* Measurements

It is often desirable to measure near-IR spectra for samples that for reasons of convenience or necessity cannot be transported to the spectrometer for 'conventional' transmission or reflectance measurements. Examples range from processes such as fermentation and refining, where on-line monitoring is desirable, to the analysis of pharmaceutical blends and incoming raw materials. A common solution is to use fibre optics or fibre-optic bundles to carry the spectral information from the sample to the spectrometer. Silica fibres are ideal for this purpose, as they are transparent from the visible through the near-IR.

One way to use fibre optics is for transmission measurements, with one bundle carrying near-IR radiation to the interface of a transmission cell, and a second bundle gathering the transmitted radiation and carrying it back to the spectrometer. Specialized fibre-optic probes exist for *in situ* transmission measurements with the 'sending'

and 'receiving' fibres in the same bundle. The immersion tip includes built-in optics to create a reproducible transmission path; light that has travelled through the sample is reflected back into the receiving fibres by a mirror built into the probe tip itself.

While transmission measurements are suitable for liquids, powders and other highly scattering samples require a different approach. One measurement simply uses a fibre-optic bundle with a measurement tip that exposes both sending and receiving fibres to the specimen. While many of the photons entering the sample are lost, a fraction of them are scattered in a path that leads them back into one of the receiving fibres. The background spectrum is typically reflectance from a ceramic standard. The 'interactance' spectrum is obtained by ratioing the single-beam powder spectrum against the single-beam ceramic reference spectrum, and reflects both the absorption properties of the sample and the wavelength dependence of the scattering efficiency. Probes based upon this general principle are suitable for checking the identity/purity of batch powder samples. The operator simply inserts the probe tip into the sample and waits for the analytical result to appear before moving onto the next measurement.

Remote Reflectance

For many production-line applications, the most convenient way to measure the near-IR spectrum is by 'remote' diffuse reflection. The source and specialized collection optics are combined in a single device and simply aimed at the target, for example chemicals or food products moving along conveyor lines or webs and sheets in a production process. Just as is the case for laboratory measurements, these instruments vary in sophistication from single-wavelength devices to full grating spectrometers – the choice of the appropriate system is dictated by the difficulty of the analysis. Because water has extraordinarily strong absorptions in the near-IR, one of the more common on-line applications is monitoring moisture content; more than one manufacturer offers near-IR filter-based analysers exclusively for this purpose.

Summary

From its original niche as a convenient method for grain analysis, near-IR spectroscopy has evolved to the point where new applications appear almost daily. The parallel evolution in hardware has led to modern instruments that could not have been contemplated by the founding fathers of near-IR analysis. Many devices faithfully produce analytical results running unattended around the clock, while others are used by operators who need not

even be aware that near-IR spectroscopy is involved. In short, the technology has reached a certain maturity.

What does the future hold? In addition to ever-faster and more accurate instruments, one exciting prospect is the full realization of the marriage of spectroscopy with imaging. Practical roadblocks to the widespread adoption of this technique are rapidly disappearing as both imaging arrays and high-throughput tunable filters become more widely accessible, and the realm of possibilities seems limitless. This and the other extraordinary instruments that appear ever-more frequently are vital to our gathering and understanding the information that nature has to offer.

Introduction

Investigations of both negative-ion and positive-ion mass spectrometry as aids to structure determination commenced in earnest in the middle of the twentieth century. The ease of formation of molecular cations, together with their characteristic fragmentations, led to the development of positive-ion mass spectrometry as one of the most important of all analytical techniques. In contrast, initial difficulties with the formation of suitable anions together with the early nonavailability of commercial mass spectrometers that could readily detect negative ions delayed the analytical development of negative-ion mass spectrometry for several decades. Modern instrumentation allows the measurement of the mass spectra of molecular anions ($M^{\bullet-}$), and of $(M-H)^-$ ions and multiply charged anions. The analytical applicability of the fragmentations of $(M-H)^-$ species will be outlined. Mechanistic information that can be obtained from gas phase studies with respect to rearrangement reactions of anions, and the collision-induced conversion of negative ions into neutrals and positive ions and the application of these techniques will also be described. Selected examples will be used to illustrate each section. References to reviews that provide further information concerning aspects of anion chemistry are listed at the end of the article.

Analytical Applications of Negative Ions

The Fragmentations of $(M-H)^-$ Species

$(M-H)^-$ ions may be formed by deprotonation of organic molecules in the chemical ionization (NICI) source of a mass spectrometer using a strong base (e.g. HO^- from H_2O or NH_2^- from NH_3), or using fast-atom bombardment (FAB), electrospray ionization (ESI), atmospheric pressure ionization (API), matrix-assisted laser desorption ionization (MALDI) mass spectrometry, and a number of associated ionization techniques. The $(M-H)^-$ ions are generally formed with little excess energy and consequently undergo little decomposition. Molecular mass information can be obtained in this way for the majority of organic compounds, including those that do not form detectable molecular cations or where peaks from such cations are of small abundance in the positive-ion spectra (examples of the latter category include many

long-chain compounds such as alcohols, ketones, acids and esters, and also some peptides and polysaccharides). Fragmentation data of $(M-H)^-$ ions may be obtained using collisional activation or some other method of energy activation of the parent anion. Ionization and energy activation techniques mentioned above are described in other articles.

The negative-ion fragmentations of $(M-H)^-$ ions derived from organic molecules are often simple and provide useful structural information. Fragmentations involving particular functional groups are often characteristic of those groups. Consider first the spectra of the two isomeric alkoxide anions shown in Figure 1. These spectra are

Figure 1 Collision-induced HO^- negative-ion chemical ionization tandem mass spectra (MS/MS) of (a) $PhCH_2CH_2O^-$ and (b) $PhCH(Me)O^-$. ZAB 2HF instrument. Argon collision gas: pressure of gas in first collision cell adjusted so that the reduction in the main beam is 10%.

**Scheme 1**

collision-induced HO^- NICI tandem mass (MS/MS) spectra that have been measured in a reverse sector mass spectrometer. The negative-ion fragmentations are rationalized in **Scheme 1**. They include simple cleavage (eqns [1] and [2]), together with reactions of an anion within an anion neutral complex (eqns [3] and [4]). A second example is shown for the $(\text{M}-\text{H})^-$ parent ion of cyclohexanone in **Figure 2**; cleavage mechanisms are outlined in **Scheme 2**. Fragmentations include a retro cleavage of the ring (eqn [5]) together with two competitive losses of dihydrogen (eqns [6] and [7]).

nucleotides and molecules containing saccharide linkages) undergo collision-induced cleavage reactions to yield stable $-\text{O}^-$ fragment anions. Negative-ion mass spectrometry is often the analytical method of choice for such molecules. A particular example is shown above for avilamycin [1], where C–O bond cleavages (the bold lines indicate the direction of charge retention) provide sequence information.

Positive-ion mass spectrometry has traditionally been the MS method of choice for sequencing peptides and proteins. However, the fragmentations of both $(\text{M}-\text{H})^-$ and $(\text{M}-n\text{H})^{n-}$ ions of peptides and proteins can also provide useful structural information. The negative-ion spectra of $(\text{M}-\text{H})^-$ ions show two types of cleavages: (i) characteristic fragmentation of the side chains of some amino acid residues (these data are summarized in **Table 1**), and (ii) cleavages of the peptide backbone. As an illustration, MS/MS data from the $(\text{M}-\text{H})^-$ parent ion of a 12-residue peptide are shown in **Figure 3**. The sequence of this peptide can be determined by the α and β negative-ion backbone cleavages shown in **Figure 3** (see **Scheme 3** for the nomenclature and mechanisms of α and β backbone cleavages). In addition, the ion formed by side-chain cleavage of CH_3CHO from the Thr side chain (cf. **Table 1**) also produces backbone cleavage ions: these are indicated by arrows in **Figure 3**.

Many biologically important molecules form $(\text{M}-\text{H})^-$ parent ions, and these often undergo characteristic fragmentations. For example, $(\text{M}-\text{H})^-$ ions from molecules containing C–O and P–O bonds (such as nucleosides,

Further negative-ion backbone cleavages are initiated by the enolate anion of an Asp or Asn side chain. This is illustrated in the spectrum of the nonapeptide shown in **Figure 4**, with the characteristic Asp backbone cleavages

Scheme 2

rationalized in **Scheme 4**. The usual α and β cleavage ions are indicated on the formula shown in **Figure 4**.

Radical Anions

Parent radical anions may be formed following low-energy electron capture by a neutral if the electron affinity of the neutral is suitably positive. Particular examples are conjugated systems (such as α -diketones, α,β -unsaturated carbonyl systems, quinones and flavones, etc) together with molecules containing specific functional groups that readily capture electrons (e.g. nitro, sulphonyl, phosphate esters, etc). For example, the limit of detection of the clonazepam [2] molecular anion is about 25 times lower than that of the corresponding molecular cation.

In some cases derivatization of a neutral with a functional group that readily accepts a low-energy electron can provide molecular mass information: for example, a long-chain alcohol can be converted into a per-fluorobenzoate ester that readily yields a molecular anion.

Table 1 Characteristic negative-ion fragmentations of side chains of amino acid residues from $(\text{M}-\text{H})^-$ ions of peptides

Residue	Loss (or formation)	Mass
Phe	PhCH_2^-	91
Tyr	$\text{pHOC}_6\text{H}_4\text{CH}_2^-$	107
	$\text{O}=\text{C}_6\text{H}_4=\text{CH}_2$	106
Trp	$\text{C}_9\text{H}_7\text{N}$	129
Ser	CH_2O	30
Thr	MeCHO	44
Cys	H_2S	34
Met	MeSH	48
	MeSMe	62
	$^+\text{CH}_2\text{CH}_2\text{SMe}$	75
Asp	H_2O	18
Glu	H_2O	18
Asn	NH_3	17
Gln	NH_3	17

Mechanistic Studies of Negative Ions

The Study of Intramolecular Rearrangements of Negative Ions

There are many rearrangement reactions of anions in the condensed phase in which the products and rates of reaction are dependent on the solvent and counterion used. The gas phase is thus the best medium for the investigation of the fundamental reactivity of the rearranging anion and the mechanism of the rearrangement. Many such rearrangements have been studied including well-known 1,2 anionic rearrangements such as the Wittig, Wolff, acyloin, negative-ion pinacol and Favorskii reactions.

The pinacol–pinacolone rearrangement (eqn [8]) is arguably the most famous of all acid-catalysed rearrangements and involves a simple Whitmore 1,2 methyl shift. Base-catalysed analogues of the pinacol rearrangement are not common, but the rearrangement does occur for deprotonated β -chlorohydrins. For example, base-catalysed rearrangement of *cis*-2-chlorocyclohexanol yields formylcyclopentane. The negative-ion pinacol rearrangement has been studied in the gas phase using MeO^- as the leaving group. This is illustrated for the reactions shown in eqns [9] and [10]. The *trans* isomer (eqn [9]) does not undergo the pinacol rearrangement, instead, an $\text{S}_{\text{N}}\text{i}$ cyclization gives an epoxide, which ring-opens as shown to yield deprotonated cyclohex-2-en-1-ol and methanol. In contrast, the *cis* isomer (see eqn [10]) undergoes the pinacol rearrangement as shown. The product anions of eqns [9] and [10] are identified from a comparison of their negative-ion mass spectra with those of independently synthesized anions.

Figure 3 Collision-induced negative-ion fast-atom bombardment tandem mass spectrum (MS/MS) of GLLEGLLGTGL(NH₂). ZAB 2HF instrument. Glycerol was used as matrix. Other details as for **Figure 1**. For the mechanisms of the backbone cleavages, see **Scheme 3**.

Scheme 3

The base-catalysed rearrangements of α -halo ketones are classical examples of the reactions of ambident enolate anions in solution. The extent of each of the two reactions shown in eqns [11] and [12] is principally a function of the type of solvent used. A protic solvent solvates more strongly at the oxygen centre of the ambident anion and thus reaction proceeds through the carbanion centre to yield the Favorskii species as the major product (eqn [11]). In marked contrast, the Favorskii rearrangement does not occur in the gas phase. Here, nucleophilic attack occurs exclusively via the more electron-rich alkoxide centre to form an allene oxide adduct that fragments as shown in eqn [13].

Figure 4 Collision-induced negative-ion fast-atom bombardment tandem mass spectrum (MS/MS) of AGLLDILGL(NH₂). ZAB 2HF mass spectrometer. Glycerol was used as matrix. Other details as for **Figure 1**. For the mechanisms of the backbone cleavages, see **Schemes 3** and **4**.

Scheme 4

Charge Reversal and Neutralization of Negative Ions

When a negative ion with high translational energy undergoes a soft collision with an inert gas atom (such as He or Ar) in a collision cell, some translational energy may be converted into internal energy. The energized ion rids itself of this internal energy in any one of a number of different ways; for example it may (i) radiate, (ii) cleave to give fragment negative ions (see, e.g. **Figures 1–4**), (iii) eject one electron to yield a neutral, or (iv) eject two

electrons (either sequentially or synchronously) to yield a positive ion. These processes may occur for either parent or daughter anions, irrespective of whether they are radical anions or even-electron anions.

Charge reversal is that process by which an anion loses two electrons to form the corresponding cation. The process is best explained by reference to the schematic diagram shown in **Figure 5**. The particular polyatomic anion under study is selected using the analyser system of a sector mass spectrometer; it then proceeds into the

first collision cell, which contains sufficient gas to effect single-collision conditions. The parent cations so produced have a range of internal energies and generally produce a mass spectrum containing peaks corresponding to the parent (cation) (the recovery signal: sometimes this is absent) together with a variety of fragment cations. The first application of charge reversal is that it is possible to make positive ions that cannot be formed by conventional ionization procedures. For example, m/z 31 from methanol in the positive mode is $\text{CH}_2=\text{OH}^+$; CH_3O^+ is not normally formed. However, CH_3O^+ can be formed by charge reversal of CH_3O^- . Similarly, RCO_2^+ is not a species formed readily by decomposition of any positive ion, but it can be formed by charge reversal of RCO_2^- .

The second application is analytical. If an $(\text{M}-\text{H})^-$ ion undergoes little or no fragmentation following excitation, another option is to charge-reverse the $(\text{M}-\text{H})^-$ to give a spectrum of positive ions that should provide structural information. Alternatively, the structure of some fragment anion may need to be determined. Comparison of

the charge-reversal spectrum of this anion with the charge-reversal spectra of anions of known structure can often identify the unknown. Suppose the major peak in a negative-ion spectrum corresponds to $\text{C}_2\text{H}_3\text{O}_2^-$ (m/z 59). The unknown is either MeCO_2^- or $^-\text{OCH}_2\text{CHO}$. The charge-reversal spectra of these anions are reproduced in **Figure 6**; each is characteristic and readily identifies the anion precursor.

Co-occurring with the charge-reversal process is that which produces an (even-electron) neutral by ejection of an electron from a radical anion, or a radical by loss of an electron from an even-electron anion. If a potential is applied after the first collision cell (see **Figure 5**) to deflect all ions, the only species proceeding into the second collision cell are neutrals formed in the first collision cell. If the second cell contains a gas (normally oxygen) that can ionize the neutrals, a composite positive-ion spectrum of all neutrals formed in the first collision cell can be obtained. This is called neutralization–reionization mass spectrometry (NRMS). The technique has a number of applications. First, the neutral formed in a negative-ion

Figure 6 Charge-reversal (positive-ion) tandem mass spectra of (a) CH_3CO_2^- and (b) $^-\text{OCH}_2\text{CHO}$. ZAB 2HF mass spectrometer. Argon collision gas: pressure adjusted in the first collision cell so that the reduction in the main beam is 10%.

fragmentation may be identified. More importantly, interesting neutrals can be synthesized in the mass spectrometer, and their structures probed both experimentally (from their mass spectra) and theoretically (using computational methods). Fred McLafferty, a pioneer in the development and application of NRMS, has stated that 'NRMS has made its largest contribution to research areas outside mass spectrometry in the characterization of unstable and radical species'. Several examples of the application of this technique are outlined below.

The radical $\text{HSO}^\bullet$ is believed to be implicated in ozone depletion in the upper atmosphere by the reactions shown in eqns [14] and [15]. This species and its isomer $\text{HOS}^\bullet$ have been made in the mass spectrometer by electron loss from the precursor anions HSO^- and HOS^- . The HOS^- precursor anion may be prepared by the collision-induced process summarized in eqn [16],

Figure 7 Neutralization-reionization mass spectra of (a) HOS^- and (b) HSO^- . Modified ZAB four-sector mass spectrometer of BEBE configuration (B = magnet sector; E = electric sector). Oxygen used as collision gas used in each collision cell (see Figure 5). The pressure of the gas in each cell was adjusted so the reduction in the main beam is 20% for each collision event. Reproduced with permission of ACS from Goldberg N and Schwarz H (1994) *Accounts of Chemical Research* 27: 347–352.

while HSO^- is prepared by admixture of H_2S and N_2O under conditions of negative-ion formation, perhaps by the reaction shown in eqn [17]. The reionization positive-ion spectra of the two non-interconverting radicals are shown in Figure 7.

There is much current interest in the formation of small cumulene and heterocumulene anions and their

Figure 8 Neutralization–reionization mass spectrum of $\text{N}\equiv\text{C}-\text{C}\equiv\text{C}-\text{O}^-$. Details as in the legend to **Figure 7**. neutrals. Two examples are mentioned. The anion $\text{N}\equiv\text{CC}\equiv\text{C}-\text{O}^-$ can be prepared by collisional activation of the precursor anion shown in eqn [18]. The corresponding radical is made by charge stripping. The positive-ion reionization spectrum of NC_3O^- is shown in **Figure 8**.

Neutral CH_2C_2 : is formed following electron loss from radical anion $\text{CH}_2\text{C}_2^{\bullet-}$. The anion is made by the reaction between allene and the monooxygen radical anion as shown in eqn [19].

Conclusions

Negative-ion mass spectrometry is a useful analytical technique that is complementary to the more ubiquitous positive-ion method. There are particular classes of compounds where the spectra of $(\text{M}-\text{H})^-$ ions provide more structural information than the corresponding positive-ion spectra.

Studies of intramolecular reactions of negative ions can provide useful mechanistic information.

Electron stripping of negative ions can be used to produce both neutrals and positive ions not available via other synthetic pathways.

Neutralization–reionization mass spectrometry (NRMS) involves the synthesis and characterization of neutral species inside a tandem mass spectrometer *via* gas-phase redox reactions. The neutrals are produced by neutralization of the corresponding mass-selected cations or anions (precursor ions) and are subsequently characterized by the mass spectra arising after reionization to positive or negative ions. The successive neutralization and reionization events are effected by collisions with gaseous targets at high kinetic energy. Equations [1] and [2] illustrate a neutralization–reionization (NR) sequence that starts with a positive precursor ion and reionizes the intermediate neutral to cations. These choices generally proceed with higher yields than alternative charge permutations and, therefore, have been employed in most NRMS studies; nonetheless, any charge combination of precursor ion and final product ions is possible and has been documented.

NRMS is uniquely suitable for the study of highly reactive neutrals that cannot be isolated and characterized in condensed phases, where interactions with neighbouring molecules would cause their immediate decomposition. By preparing the neutrals in the gas phase of the mass spectrometer, such destructive intermolecular collisions are avoided. Furthermore, the ionized forms of reactive neutrals are often stable, well-known ions that can easily be generated in the mass spectrometer to serve as the starting material for the neutrals' synthesis. For example, the carbene ion $\text{H}-\text{C}-\text{NH}_2^{+\bullet}$, which is available *via* electron ionization (EI) of cyclopropyl amine, can be used to synthesize the highly reactive prototype carbene

$\text{H}-\text{C}-\text{NH}_2$ (a putative interstellar species); similarly, the distonic ion $\bullet\text{CH}_2\text{CH}_2\text{OCH}_2^+$, which is formed by EI of 1,4-dioxane, can serve as the precursor for the hypovalent 1,4-diradical $\bullet\text{CH}_2\text{CH}_2\text{OCH}_2^\bullet$, i.e. ring-opened oxetane (pyrolysis intermediate). NRMS has enabled the first experimental characterization of a large variety of neutral intermediates, in particular species with weak bonds, extra or missing valences, unpaired electrons, or a high tendency toward intermolecular isomerization (see below).

Knowledge of the intrinsic properties of such unusual neutrals is desirable for many reasons. They are postulated key intermediates in organic and biological reactions; they appear in the atmosphere, in interstellar clouds, and in other cosmic environments; they are involved in plasma and combustion chemistry and in photochemical processes and they play an important role in industrial and biological catalysis.

NRMS Instrumentation

NRMS experiments are conducted with beam tandem mass spectrometers consisting of two mass-analyzing devices (MS-1 and MS-2) and equipped with at least two collision cells and an intermediate ion deflector in the field-free region between MS-1 and MS-2 (**Figure 1**). The desired precursor ion, i.e. the cationic or anionic form of the reactive neutral to be synthesized, is generated by the appropriate ionization method in the ion source, accelerated to a keV kinetic energy (3–10 keV), and separated from all other ions simultaneously

Figure 1 Basic components of a mass spectrometer for NRMS.

produced in the ion source by MS-1. The mass-selected precursor ion beam is then partly neutralized by charge exchanging collisions with the neutralization target (eqn [1]) in the collision cell following MS-1 (neutralization cell). The mixture of neutrals and ions exiting the cell passes the ion deflector, where the ions are removed from the beam path by electrostatic deflection. The remaining neutral beam subsequently enters the next collision cell (reionization cell) where it is ionized by collisions with the reionization target (eqn [2]). The newly formed product ions are then dispersed according to their mass-to-charge ratio (m/z) by MS-2 to yield the NR spectrum of the precursor ion under study.

MS-1 and MS-2 may be simple, one-stage mass analyzers or tandem mass spectrometers. In the latter case, it is possible to form precursor ions by MS/MS of *specific* source-generated ions, and/or to analyze by MS/MS a *specific* product ion arising in the reionization event. Generally, the lifetimes of the ions subjected to NRMS experiments have been in the order of tens of microseconds. Depending on the distance between neutralization and reionization cells, the lifetimes of the neutrals generated in NRMS experiments range between a few tenths of a microsecond to a few microseconds. The field-free region between MS-1 and MS-2 may contain a third collision cell and a second intermediate ion deflector. Such a configuration allows one (a) to vary the lifetime of the neutral intermediates (by changing the neutralization and/or reionization cell) and (b) to probe the collisionally activated dissociation (CAD) of the neutrals *before* they are reionized.

The Neutralization and Reionization Events

Positive or negative precursor ions can be subjected to neutralization and the resulting neutral species may be reionized to cations or anions. Customarily, the charges of precursor and final ions are indicated by superscripts to the NR acronym. The most frequently performed experiment is $^+NR^+$; it involves neutralization of a cation followed by reionization of the neutral intermediate(s) to cations, i.e. a gas phase reduction–oxidation succession.

Cations with kinetic energies in the keV range can be neutralized with metal vapours (e.g. Na or Hg), atomic or molecular gases (e.g. Xe or $(CH_3)_3N$), and organic compound vapours (e.g. CH_3SSCH_3). Electron exchange takes place during the collision encounter of the fast moving precursor ion with the essentially stationary target atom/molecule. This encounter lasts only femto-seconds, a time much shorter than typical rovibrational periods. As a result, such neutralization is *vertical*,

Figure 2 Franck–Condon energies in vertical neutralization of the pyridinium ion. Reprinted with permission of John Wiley and Sons from Turecek F (1998) Modelling nucleobase radicals in the mass spectrometer. *Journal of Mass Spectrometry* 33: 779–795.

generating the incipient neutral in the geometry of its ionic precursor (Franck–Condon process, see **Figure 2**).

The neutralization yield and internal energy of the neutral species generated in the neutralization step (eqn [1]) depend on several variables, including the internal energy of the precursor ion, the equilibrium geometries of precursor ion and neutral, and the target used for neutralization. One important factor determining the internal energy of the incipient neutral species emerging upon vertical neutralization is the thermochemistry of the charge exchange process.

The enthalpy change of this reaction, ΔH_N , is given in eqn [3], where $IE_v(T_1)$ is the vertical ionization energy of the gaseous target oxidized and $RE_v(\text{ABCD}^+)$ the vertical recombination energy of the precursor ion reduced.

$$\Delta H_N = IE_v(T_1) - RE_v(\text{ABCD}^+) \quad [3]$$

Exothermic neutralization ($\Delta H_N < 0$) usually leads to an excited species which may fragment if the energy

deposited (ΔH_N) exceeds the dissociation threshold. On the other hand, thermoneutral ($\Delta H_N = 0$) or endothermic ($\Delta H_N > 0$) neutralizations normally yield ground-state neutrals. With endothermic encounters, the energy deficit is supplied by the kinetic energy of the precursor ion. In general, thermoneutral or nearly thermoneutral reactions exhibit the highest yields.

It is believed that neutralization involves glancing collisions with a relatively large projectile–target distance ('impact parameter'). An endothermic neutralizing collision may provide some extra internal energy to the newly formed neutral; the degree of activation in the nascent neutral increases with ΔH_N , presumably because of the decreased impact parameter needed to convert some kinetic into internal energy, so that charge exchange becomes thermochemically possible. Additional excitation may be imparted by Franck–Condon effects; thus, if the equilibrium geometries of $ABCD^+$ and $ABCD$ differ substantially, $ABCD$ can emerge with rovibrational excitation, even if it is formed by a thermoneutral or endothermic process. For example, endothermic neutralization of pyridinium cations produces vibrationally excited pyridinium radicals due to the different ground-state structures of cation and radical (Figure 2). The average internal energy imparted to the radical by Franck–Condon effects (E_{FC}) is $\sim 20 \text{ kJ mol}^{-1}$ in this case. This modest amount is not sufficient to cause N–H bond cleavage in the radical ($D = 108 \text{ kJ mol}^{-1}$), but increases the dissociation extent after reionization. In some systems, Franck–Condon effects can be very large; this is true for the neutralization of ground-state $(\text{CH}_3)_2\text{Si}^+\text{OH}$, which produces the radical $(\text{CH}_3)_2\text{Si}^+\cdot\text{OH}$ with enough internal energy for O–H or C–Si bond cleavage; therefore, such radicals do not survive intact until reionization, although $(\text{CH}_3)_2\text{Si}^+\text{OH}$ is a bound species in its ground state. When molecular targets are used for neutralization, Franck–Condon effects play a more significant role than the thermochemistry of the neutralization reaction in determining the energy state of $ABCD$; further, in exothermic neutralizations, the excess ΔH_N can end up as excitation of the target ion (T_1^+ in eqn [1]) and not in the incipient neutral $ABCD$. The energy state of $ABCD$ also depends on the internal energy of the precursor ion $ABCD^+$; an activated precursor ion can give rise to an activated or vibrationally cool neutral, depending on the Franck–Condon overlap of eqn [1]. The former case is true for NH_4^+ neutralization, while the latter behaviour has been observed for neutralized $(\text{CH}_3)_2\text{OH}^+$, $\text{C}_2\text{H}_5\text{OH}_2^+$, and $(\text{CH}_3)_2\text{Si}^+\text{OH}$. Finally, it must be kept in mind that the neutralizing collision (eqn [1]) may also cause some CAD of the precursor ion. The extent of concomitant CAD is minimized by avoiding strongly endothermic neutralizations whose small impact parameters may excite and dissociate the precursor ion (see above).

In the second $^+\text{NR}^+$ step (eqn [2]), the neutral intermediate ($ABCD$) is collisionally reionized. This process, which resembles ionization by electron impact, produces a molecular ion as well as fragment ions (see eqn [2]). Customarily, the molecular ion ($ABCD^+$) has been called the 'survivor ion', as it originates from $ABCD$ that survived intact. The survivor ion gives rise to the 'recovery peak' in the NR spectrum, i.e. the peak appearing at the same m/z value as the precursor ion. Regarding the reionization target (T_2 in eqn [2]), O_2 and He are the most widely employed choices. O_2 yields more abundant recovery peaks and He more fragments, justifying their classification as 'softer' and 'harder' reionization gases, respectively. Other less frequently used soft reionization gases are NO and NO_2 . Reionization efficiencies depend significantly on the structure of the neutral and rise with the neutral's kinetic energy but decline with its internal energy. Furthermore, kinetic and internal energies of the neutral intermediate also affect how much internal energy is deposited on collisional ionization; here, the average internal energy gained increases with both.

With anionic precursors, the neutralization step entails electron removal, i.e. an oxidation reaction, as does reionization of a neutral to cations. Therefore, O_2 , which is the best reionization target (see above), also is the target of choice for the neutralization of anions. Conversely, cation neutralization targets, which effect a gas-phase reduction, are most suitable for reionization to anions. Widely used targets for this purpose have been xenon and trimethylamine. Reionization to anions suffers from substantially poorer yields than reionization to cations, often by ca. 10 times or more; therefore, it has been employed to a much lesser extent. However, in certain cases it can provide superior structural information, for example, the unequivocal identification of oxygen-centered radicals, such as the carbonate radical $\text{CO}_3^\cdot$ and the diradical $^\cdot\text{CH}_2\text{CH}_2\text{O}^\cdot$ relied on their reionization to anions.

The Study of Reactive Neutrals *via* NRMS

The stability and unimolecular reactivity of the neutral generated in the neutralization step are characterized by the mass spectrum arising after reionization. The presence of a recovery peak in this spectrum provides evidence that the neutral intermediate has survived intact (i.e. undissociated) for microsecond(s). Whether it has retained the connectivity of the precursor ion is judged by comparison of the NR spectrum to the CAD spectrum of the precursor ion or the NR spectra of other, usually stable and known isomers. Both these strategies are presented below with representative examples.

The hypermetallic dilithium fluoride (Li_2F), a compound violating the octet rule, can be formed in the gas phase by neutralizing the known cation $[\text{Li}-\text{F}-\text{Li}]^+$, which is produced abundantly upon fast atom bombardment ionization of lithium trifluoroacetate. Neutralization with trimethylamine (TMA) and subsequent reionization with O_2 lead to the NR spectrum of **Figure 3a**. The CAD spectrum of $[\text{Li}-\text{F}-\text{Li}]^+$ (using O_2) is displayed in **Figure 3b**. The significant recovery peak in the NR spectrum convincingly shows that Li_2F has survived intact. It is, thus, a stable species and bound in respect to $\text{Li} + \text{LiF}$. The experimentally documented

Figure 3 (a) Neutralization-reionization ($^+\text{NR}^+$) and (b) collisionally activated dissociation (CAD) spectra of Li_2F^+ . Reprinted with permission of Elsevier from Polce MJ and Wesdemiotis C (1999) Hypermetallic dilithium fluoride, Li_2F , and its cation and anion: A combined dissociation and charge permutation study. *International Journal of Mass Spectrometry* 182/183: 45–52.

stability is supported by theory which predicts that the reaction $\text{Li}_2\text{F} \rightarrow \text{Li} + \text{LiF}$ must overcome a barrier of $130\text{--}140 \text{ kJ mol}^{-1}$. The fragmentation patterns in NR and CAD spectra of **Figure 3** are similar. In both spectra, the most intense fragments are $\text{LiF}^{+\bullet}$ (m/z 26) and F^+ (m/z 19), and the peak widths at half-height ($w_{0.5}$) follow the order $w_{0.5}(\text{LiF}^{+\bullet}, \text{Li}^+) < w_{0.5}(\text{Li}_2^+) < w_{0.5}(\text{F}^+)$. These common trends strongly suggest that the majority of NR fragments arise from decomposing survivor ions, not from dissociation of the intermediate Li_2F , in keeping with the considerable thermodynamic stability of this hypermetallic compound.

A reactive neutral that dissociates extensively in the time span between neutralization and reionization is the diradical $^{\bullet}\text{CH}_2\text{CH}_2\text{OCH}_2^{\bullet}$ (C–C ring-opened oxetane). This species is available through neutralization of the distonic ion $^{\bullet}\text{CH}_2\text{CH}_2\text{OCH}_2^+$ which is generated by electron ionization of 1,4-dioxane (**Scheme 1**). When Xe and O_2 are used for neutralization and reionization, respectively, the NR spectrum of **Figure 4a** is obtained; it is dominated by peaks at $m/z \leq 30$, verifying that the incipient diradical emerging in the neutralization step decomposes to ethylene (28 Da) and formaldehyde (30 Da). A small fraction remains, however, undissociated, as indicated by the presence in **Figure 4a** of a survivor ion (m/z 58) and fragment ions of $m/z > 30$. The surviving diradicals could cyclize to the thermodynamically more stable oxetane molecule (cf. **Scheme 1**). Whether this happened is best determined by comparison of the NR spectra of $^{\bullet}\text{CH}_2\text{CH}_2\text{OCH}_2^+$ (**Figure 4a**) and ionized oxetane (**Figure 4b**). Consistent with the high stability of neutral oxetane, the corresponding NR spectrum (**Figure 4b**) contains a substantial recovery peak (m/z 58); further, the $\text{C}_3\text{H}_{0-3}^+$ fragments in this spectrum (m/z 36–39) are diagnostic for oxetane's cyclic structure which has three adjacent C atoms. These latter fragments are minuscule in the NR spectrum of $^{\bullet}\text{CH}_2\text{CH}_2\text{OCH}_2^+$ (**Figure 4a**), which shows that the diradical $^{\bullet}\text{CH}_2\text{CH}_2\text{OCH}_2^{\bullet}$ does not cyclize to oxetane within the time available between neutralization and reionization. Hence, the diradical is kinetically stable with respect to both isomerization and dissociation and exists as a bound, high-energy intermediate.

Scheme 1

Auxiliary NRMS Methods

When the precursor ion is not isomerically pure or the intermediate neutrals rearrange partly or dissociate to products that are isobaric with those arising after reionization of the surviving neutrals, a straightforward characterization from the NR spectrum alone may be impossible. This problem has led to the development of an array of auxiliary NRMS methods that can be used to explore the stability and unimolecular reactivity of transient neutrals with complex and/or ambiguous NR spectra. A brief overview of these experimental approaches follows, along with examples demonstrating their usefulness.

NRMS-CAD Studies

The isomerization proclivity of a reactive intermediate can be interrogated by measuring the tandem mass spectrum of the survivor ion. This capability requires

Figure 4 Neutralization-reionization ($^+NR^+$) spectra of (a) $^+CH_2CH_2OCH_2^+$ and (b) oxetane cation. Reprinted with permission of the American Chemical Society from Polce MJ and Wesdemiotis C (1993) The unimolecular chemistry of the 1,4-diradical $^+CH_2CH_2OCH_2^+$ in the gas phase. Scheme 2

that the instrumentation available be equipped with an additional mass analyzing device after the one used for the mass separation of the NR products. The NRMS-CAD method is illustrated with the CH_3NO tautomers depicted in **Scheme 2**.

Formimidic acid and aminohydroxycarbene, both tautomers of formamide, are reactive molecules that do not exist in condensed media. Using NRMS, they can be synthesized in the gas phase from the corresponding radical cations, which are formed *via* dissociative electron ionization of *N*-formylhydrazone (yields the iminol ion) and oxamide (yields the carbene ion). After reionization, all three tautomers give rise to abundant survivor ions, but the NR spectra are not distinctive enough to unequivocally determine whether the less stable iminol and carbene neutrals undergo isomerization to the most stable formamide molecule. This question can be answered by subjecting the three survivor ions to CAD and comparing the resulting spectra to the CAD spectra of authentic (i.e. source-generated) amide, iminol, and carbene ions (**Figure 5**). The ions are known not to interconvert.

The NR-CAD and CAD spectra of formamide and the carbene are essentially indistinguishable, providing strong evidence that the amide and carbene tautomers retain their structures upon NR and do not undergo any rearrangements. In sharp contrast, NR-CAD and CAD

Figure 5 Partial CAD spectra (using He) of $^+NR^+$ survivor ions (top) and CAD spectra of source-generated ions (bottom) of $H_2N-C(H)=O^{*+}$ (left), $HN=C(H)OH^{*+}$ (centre), and $H_2N-C-OH^{*+}$ (right). Reprinted with permission of Elsevier from McGibbon GA, Burgers PC, and Terlouw JK (1994) The imidic acids $H-N=C(H)-OH$ and $CH_3-N=C(H)-OH$ and their tautomeric carbenes $H_2N-C-OH$ and $CH_3-N(H)-C-OH$: Stable species in the gas phase formed by one-electron reduction of their cations. *International Journal of Mass Spectrometry and Ion Processes* 136: 191–208.

spectra of the iminol ion differ markedly from each other; the NR-CAD spectrum can be interpreted as a combination of the CAD spectra of genuine amide and iminol ions, in agreement with a partial tautomerization of the neutral iminol to the amide.

CAD of the Neutral Intermediate (NCR Studies)

Instruments with three successive collision cells and two intermediate ion deflectors allow for CAD of the neutral intermediate before reionization. With such an arrangement, the neutral is produced in the first cell, undergoes CAD in the second cell, and is reionized (along with its dissociation and/or isomerization products) in the third collision cell. The first deflector removes unneutralized precursor ions and the second one any ions formed during the neutral CAD step. This procedure gives rise to an NCR spectrum (neutralization – CAD – reionization) which, when compared to the corresponding NR spectrum, reveals insight about the favoured fragmentation and/or isomerization of the neutral species under study.

As an example, **Figure 6** shows the NR and NCR spectra of the distonic ion ${}^+\text{CH}_2\text{CH}_2\text{O}^\bullet$ whose neutralization creates the elusive diradical ${}^\bullet\text{CH}_2\text{CH}_2\text{O}^\bullet$.

Figure 6 (a) Neutralization-reionization (${}^+\text{NR}^+$) and (b) neutralization–CAD–reionization (${}^+\text{NCR}^+$) spectra of ${}^+\text{CH}_2\text{CH}_2\text{O}^\bullet$. Hg was used for neutralization, O_2 for reionization, and He for CAD. Reprinted with permission of the American Chemical Society from Wesdemiotis C, Leyh B, Fura A, and McLafferty FW (1990) The isomerization of oxirane. Stable ${}^\bullet\text{CH}_2\text{OCH}_2^\bullet$, ${}^\bullet\text{CH}_2\text{CH}_2\text{O}^\bullet$, and ${}^\bullet\text{CHOCH}_3$ and their counterpart ions. *Journal of the American Chemical Society* 112: 8655–8660.

(ring-opened oxirane, cf. **Scheme 3**). The increased relative abundances of m/z 43, 29, 28, and 12–15 in the NCR spectrum support the occurrence of the top channel in **Scheme 3** (dissociation through acetaldehyde). Corroborative evidence that collisionally activated ${}^\bullet\text{CH}_2\text{CH}_2\text{O}^\bullet$ partially interconverts to $\text{CH}_3\text{CH}=\text{O}$, but does not ring-close to oxirane, is obtained by the NR-CAD spectrum of ${}^+\text{CH}_2\text{CH}_2\text{O}^\bullet$ (see previous section), which is consistent with a mixture of ${}^+\text{CH}_2\text{CH}_2\text{O}^\bullet$ and $\text{CH}_3\text{CH}=\text{O}^{+\bullet}$ and significantly different from the reference CAD spectrum of oxirane ion.

Photodissociation/Photoionization of the Intermediate Neutrals

Laser light can be used, in place of the reionization gas, to probe the reactivity and electronic state(s) of the neutrals produced in the neutralization step. Due to the low neutral currents generated in NRMS experiments ($\sim 10^6$ molecules per second), a coaxial arrangement of the neutral and laser beams and continuous laser light are necessary to ensure detectable photodissociation or photoionization yields. An argon laser, which emits intense lines at 488 nm (2.54 eV) and 514.5 nm (2.41 eV), is suitable for such experiments. The procedure is illustrated for the hypervalent radical $\text{ND}_4^\bullet$.

Collisional neutralization of ND_4^+ followed by laser irradiation of $\text{ND}_4^\bullet$ gives rise to the NR spectrum of **Figure 7**, top. A second NR spectrum is acquired with the laser off so that the contribution of the background gases can be assessed. Subtraction of these sequential spectra gives the net change due to interaction with photons (**Figure 7**, bottom). The background-corrected spectrum includes a very weak positive contribution to the ND_4^+ survivor ion at m/z 22, indicating that the $\text{ND}_4^\bullet$ beam contains a minor fraction of long-lived excited electronic states with ionization energies ≤ 2.54 eV; for comparison, the IE of ground-state $\text{ND}_4^\bullet$ is 4.6 eV. The corrected NR spectrum also shows increased intensities of $\text{ND}_3^{+\bullet}$ (m/z 20) and ND_2^+ (m/z 18), which are attributed to photodissociation of ground-state $\text{ND}_4^\bullet$.

Scheme 3

Figure 7 Neutralization–photodissociation / photoreionization spectrum of ND_4^+ . Top: total reionization, bottom: after background subtraction. ND_4^+ was formed by ND_4^+ neutralization with dimethyl disulfide. Reprinted with permission of Elsevier from Sadilek M and Turecek F (1996) Laser photolysis of ND_4^+ and trimethylamine formed by collisional neutralization of their cations in the gas phase. *Chemical Physics Letters* 263: 203–308.

and subsequent collisional reionization with the background gases. The alternative scenario, namely collisional reionization to ND_4^+ followed by photodissociation of ND_4^+ to $\text{ND}_3^{+\bullet}$ and ND_2^+ is energetically impossible with the wavelengths used.

Variable-Time NRMS

A given NR product may arise from dissociation of the survivor ion or from dissociation of the neutral intermediate (see above). As explained above, NCR helps identify the predominant neutral fragmentations. An alternative approach for distinguishing overlapping neutral and ion dissociations is to systematically alter the time scales of these processes, using variable-time NRMS; here, the position of the reionization cell is varied, in order to change the *lifetimes* ('observation times') of the neutrals (ABCD) and reionized ions (ABCD⁺ plus fragments). The cell need not be moved physically; instead, a segmented reionization cell can be used, in which the segments are individually floatable so that ions formed inside them are either prevented or permitted passage to MS-2, depending on the potentials applied. This essentially corresponds to moving the entrance of the reionization cell; if the segments are floated such that the entrance moves towards (away from) MS-2, the observation time of the neutrals increases (decreases). Since the field-free region housing of the NR cells has a fixed length, increasing the observation time of the neutrals decreases that of the reionized ions (time elapsing between their formation and MS-2 entry) and *vice versa*.

Figure 8 shows partial variable-time NR spectra of the dimethylsulfonium cation, $(\text{CH}_3)_2\text{SH}^+$, in which the lifetime of neutral $(\text{CH}_3)_2\text{SH}^\bullet$ (a hypervalent radical) gradually increases from 0.35 to 1.76 μs while that of the reionized ions decreases from 3.44 to 2.02 μs . The relative

Figure 8 Variable-time $^+\text{NR}^+$ spectra of $(\text{CH}_3)_2\text{SH}^+$ formed by chemical ionization of $(\text{CH}_3)_2\text{S}$ with $(\text{CH}_3)_2\text{CH}=\text{OH}^+$. Dimethyl disulfide and oxygen served as the neutralization and reionization targets, respectively. The observation times of the neutrals are 0.35 μs (left), 1.05 μs (centre), and 1.76 μs (right). The corresponding observation times of the ions are 3.44 μs (left), 2.73 μs (centre), and 2.02 μs (right). Reprinted with permission of Elsevier from Sadilek M and Turecek F (1999) Metastable states of dimethylsulfonium radical, $(\text{CH}_3)_2\text{SH}^\bullet$: A neutralization–reionization mass spectrometric and ab initio computational study. *International Journal of Mass Spectrometry* 185/186/187: 639–649.

abundance of the survivor ion (designated 1H^+) decreases upon increasing the observation time of the neutrals (equivalent with time available for neutral dissociation). This clearly points out that a fraction of radical $(\text{CH}_3)_2\text{SH}^\bullet$ dissociates in the microsecond time scale and that the peak labelled $1^+\bullet$ primarily originates through the neutral dissociation $(\text{CH}_3)_2\text{SH}^\bullet \rightarrow (\text{CH}_3)_2\text{S} + \text{H}^\bullet$ and subsequent reionization of $(\text{CH}_3)_2\text{S}$.

Another example is illustrated in **Figure 9**, which depicts variable-time NR spectra of the methylthiomethyl cation, $\text{CH}_3\text{SCH}_2^+$. In this case, the observation times for $\text{CH}_3\text{SCH}_2^\bullet$ and its reionization products are 2.44 and 1.70 μs , respectively, in the top and 0.36 and 3.78 μs , respectively, in the bottom spectrum. Now, the relative abundance of the survivor ion exhibits a sixfold decrease upon decreasing the minimum neutral lifetime from 2.44 to 0.36 μs while increasing that of reionized $\text{CH}_3\text{SCH}_2^+$ from 1.70 to 3.78 μs . Thus, the depletion of the survivor ion in the lower spectrum must be due to an increased fraction of reionized $\text{CH}_3\text{SCH}_2^\bullet$ that dissociates. This, in turn, strongly suggests that (a) the fraction of $\text{CH}_3\text{SCH}_2^\bullet$ dissociating within microseconds is negligible and (b) collisional reionization of $\text{CH}_3\text{SCH}_2^\bullet$ is accompanied by substantial energy deposition, thereby

Figure 9 Variable time $^+NR^+$ spectra of $CH_3SCH_2^+$ using $(CH_3)_3N$ for neutralization and O_2 for reionization. The observation times for $CH_3SCH_2^+$ and reionized $CH_3SCH_2^+$ are (a) 2.44 and 1.70 μs and (b) 0.36 and 3.78 μs , respectively. Reprinted with permission of the American Chemical Society from Kuhns DW, Tran TB, Shaffer SA, and Turecek F (1994) Methylthiomethyl radical. A variable-time neutralization-reionization and ab initio study. *Journal of Physical Chemistry* 98: 4845–4853.

extending the unimolecular decomposition of the reionized ions into the microsecond time window.

Neutral and Ion Decomposition Difference (NIDD)

In this method, a neutral produced from an *anionic* precursor is reionized to *cations*, and one produced from a *cationic* precursor is reionized to *anions*, to thus obtain a $^-NR^+$ or $^+NR^-$ spectrum, respectively. This is then compared to the corresponding charge reversal spectrum ($^-CR^+$ or $^+CR^-$) of the precursor ion, where charge inversion is afforded by a two-electron transfer in a *single* collision (either of the two collision cells in **Figure 1** can be used for this purpose). Under *single* collision conditions, the CR signals originate solely through ionic fragmentations of the charge-inverted ions. In contrast, the NR signals, which result from two spatially separated collisions involving neutral intermediates, may arise *either* from the neutral *or from* the reionized ions. Normalization of the spectra to the sum of all fragments followed by subtraction of the CR from the NR intensities (eqn [4]) results in the NIDD spectrum, in which processes due to the fragmentation of the neutrals have positive intensities, while ionic contributions (of the reionized ions) show up as negative peaks. Hence, the neutral and ionic processes of NR are readily deconvoluted.

$$I_i(\text{NIDD}) = \left[I_i(\text{NR}) / \sum_i I_i(\text{NR}) \right] - \left[I_i(\text{CR}) / \sum_i I_i(\text{CR}) \right] \quad [4]$$

where I_i is the intensity of the i th ion.

Figure 10 (a) Neutralization–reionization ($^-NR^+$) spectrum of *n*-butoxide anions using O_2 for neutralization and reionization. (b) Charge reversal ($^-CR^+$) spectrum of *n*-butoxide anions using O_2 . (c) $^-NIDD^+$ spectrum of *n*-butoxide anions. Reprinted with permission of Wiley-VCH from Hornung G, Schalley CA, Dieterle M, Schröder D, and Schwarz H (1997) A study of the gas-phase reactivity of neutral alkoxy radicals by mass spectrometry: α -cleavages and Barton-type hydrogen migrations. *Chemistry: A European Journal* 3: 1866–1883.

NIDD is most suitable for the study of anionic precursors, which easily undergo two-electron loss in one step. The method has been applied extensively to alkoxide anions to decipher the chemistry of the corresponding radicals and cations, both of which are more reactive and less readily accessible than the anions. As an example, **Figure 10** shows the $^-NR^+$, $^-CR^+$, and $^-NIDD^+$ spectra of the *n*-butoxide anion, $CH_3CH_2CH_2CH_2O^-$. Three prominent features are worth mentioning: (a) The recovery peaks are weak, consistent with the high reactivity expected for the oxonium cation $CH_3CH_2CH_2CH_2O^+$. (b) The favoured dissociations of this elusive cation are identified by the negative signals in **Figure 10c** and

**Scheme 4****Table 1** Examples of elusive neutral intermediates that have been synthesized and characterized by NRMS

Intermediate type	Examples
Ylides	$\text{H}_2\text{N}^+=\text{N}^-$ (<i>iso</i> -diazine), $^-\text{HC}=\text{N}^+=\text{NH}$ (nitrileimine), $^-\text{HC}=\text{N}^+=\text{CH}_2$ (<i>N</i> -methyllide of HCN), $\text{C}_3\text{H}_3\text{NS}$ (thiazole-2-ylide), $\text{C}_5\text{H}_5\text{N}$ (pyridine-2-ylide)
Carbenes	$\text{H}-\text{C}-\text{NH}_2$ (aminocarbene), $\text{H}-\text{C}-\text{NO}_2$ (nitrocarbene), $\text{H}_2\text{N}-\text{C}-\text{NH}_2$ (diaminocarbene), $\text{HO}-\text{C}-\text{OH}$ (dihydroxycarbene), $:\text{C}=\text{C}=\text{O}$ (carbonyl carbene), $\text{CH}_3\text{O}-\text{C}-\text{OCH}_3$, $\text{H}-\text{C}-\text{OC}_2\text{H}_5$ (ethoxycarbene), $:\text{C}=\text{C}(\text{H})\text{CN}$ (cyanovinylidene), $\text{C}_3\text{H}_4\text{N}_2$ (imidazol-2-ylidene and imidazol-4-ylidene), $\text{C}_3\text{H}_5\text{NO}$ (2-oxazolidinylidene), $\text{H}_2\text{CCCC:}$, $\text{CH}_3\text{O}-\text{C}-\text{OCH}_2\text{CF}_3$
Cumulenes	$\text{O}=\text{C}=\text{C}=\text{O}$ (ethylenedione), NNCCN^* , NCNCCN^* , NCCO^* , CNCO^* , CCNO^* , OCCN^*O , OCN^*CO , NCCO_2^* , NCNCS , $\text{O}=\text{C}=\text{C}=\text{C}=\text{O}$ (carbon suboxide), NCCCO^* , $\text{O}=\text{C}=\text{C}=\text{CH}-\text{CO}_2\text{H}$
Radicals	HOSO_2^* (bisulfite radical), HOCO_2^* (bicarbonate radical), $\text{FC}^*(\text{OH})_2$, $\bullet\text{CH}_2\text{NHNH}_2$, $\bullet\text{CH}_2\text{CH}_2\text{Br}$, $\bullet\text{CH}_2\text{N}(\text{H})-\text{COOH}$, $\text{H}_2\text{NCH}_2\text{C}^*(\text{OH})_2$, $(\text{CH}_3)_2\text{NCH}_2^*$, $\text{CH}_3\text{CH}_2\text{C}^*(\text{OH})_2$, $\text{C}_4\text{H}_6\text{N}^*$ (neutral form of C-2 and C-3 protonated pyrrole), $\text{C}_4\text{H}_6\text{N}^*$ (neutral form of N-3 protonated imidazole), $\text{C}_4\text{H}_5\text{N}_2^*$ (neutral form of protonated pyrimidine), $\text{C}_4\text{H}_6\text{N}_3^*$ (neutral form of protonated 2- or 4-pyrimidinamine)
Hypervalent radicals	$\text{CH}_2=\text{CH}(\text{OH})_2^*$, $\text{C}_2\text{H}_5\text{OH}_2^*$, $(\text{C}_2\text{H}_5)_3\text{O}^*$, $n\text{-C}_7\text{H}_{13}\text{O}^*\text{H}(\text{CH}_3)$, $\text{CH}_3\text{O}(\text{CH}_2)_n\text{OH}^*(\text{CH}_3)$ ($n=2,4$), $(\text{CH}_3)_2\text{N}^*\text{H}_2$ (several isotopomers), $\text{H}_3\text{N}^*\text{CH}_2\text{CO}_2\text{H}$, $(\text{CH}_3)_3\text{N}^*\text{H}$, $(\text{CH}_3)_4\text{N}^*$, $n\text{-C}_6\text{H}_{11}\text{N}^*\text{H}_3$, $\text{C}_6\text{H}_5\text{CH}_2\text{N}^*\text{H}_3$, $(\text{C}_2\text{H}_5)_4\text{N}^*$, $n\text{-C}_6\text{H}_{11}\text{N}^*\text{H}(\text{CH}_3)_2$, $\text{C}_6\text{H}_5\text{CH}_2\text{N}^*\text{H}_2(\text{CH}_3)$, $n\text{-C}_7\text{H}_{15}\text{N}^*\text{H}(\text{CH}_3)_2$, $\text{C}_6\text{H}_5\text{CH}_2\text{N}^*\text{H}(\text{CH}_3)_2$, $\text{C}_6\text{H}_5\text{N}^*(\text{CH}_3)_3$, $\text{C}_6\text{H}_5\text{CH}_2\text{N}^*(\text{CH}_3)_3$, $\text{C}_6\text{H}_5\text{CH}_2\text{N}^*(\text{C}_2\text{H}_5)_3$, $\text{HN}(\text{CH}_2\text{CH}_2)_2\text{N}^*\text{H}(\text{CH}_3)$, $\text{N}(\text{CH}_2\text{CH}_2)_3\text{N}^*\text{H}$, $\text{CH}_3\text{N}(\text{CH}_2\text{CH}_2)_2\text{N}^*\text{H}(\text{CH}_3)$, $(\text{CH}_3)_2\text{N}(\text{CH}_2)_n\text{N}^*\text{H}(\text{CH}_3)_2$ ($n=2,3,4,6$), $(\text{NO}_2)_2\text{C}_6\text{H}_4\text{CH}_2\text{N}^*\text{H}(\text{CH}_3)_2$, $\text{C}_6\text{F}_5\text{CH}_2\text{N}^*\text{H}(\text{CH}_3)_2$, $(\text{C}_2\text{H}_5)_2\text{X}^*$ ($\text{X}=\text{Cl}, \text{Br}, \text{I}$), H_3S^* (various isotopomers)
Diradicals	$\bullet\text{CH}_2\text{OSi}^*$, $\bullet\text{CH}_2\text{NHCH}_2^*$, $\bullet\text{CH}_2\text{COO}^*$ (acetoxo), $\bullet\text{CH}_2\text{CH}_2\text{OCH}_2^*$, $\bullet\text{CH}(\text{CH}_3)\text{OCH}_2^*$, $\bullet\text{CH}_2\text{CH}_2\text{CH}(\text{OH})^*$, $\bullet\text{CH}_2\text{CH}_2\text{SCH}_2^*$, $\bullet\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}(\text{OH})^*$
Intermediates in atmospheric chemistry	NH_2NO (nitrosamine), HSO^* , SOH^* , HSOH (hydrogen thioperoxide), SOH_2 (thiooxonium ylide), $\text{O}=\text{S}^*\text{OH}$ (hydroxysulfinyl radical), $\text{O}_2\text{S}^*\text{H}$ (hydrogensulfonyl radical), HOSO_2H (sulfonic acid), CH_3SCH^* , $(\text{CH}_3)_2\text{S}^*\text{OH}$
Clusters	NSS , SNS (nitrogen disulfide), SSNS , O_2SOSO (sulfur dioxide dimer), $\text{He}@C_{60}$
Reactive closed-shell species	HOSSOH (dihydroxy disulfide), FCO_2H (fluoroformic acid), RCONO ($\text{R}=\text{H}, \text{CH}_3, \text{CF}_3$), $\text{HC}\equiv\text{NS}$ (thiofulminic acid), $\text{CH}_3\text{O}-\text{P}=\text{O}$, $\text{CH}_3\text{S}-\text{P}=\text{O}$, CH_3PS_2 , $\text{CH}_3\text{S}-\text{P}=\text{S}$, $\text{CH}_3\text{C}\equiv\text{NS}$, $\text{CH}_3\text{H}_7\text{NO}$ (3-methyl-2-aziridinone), $\text{CH}_3\text{CH}=\text{CH}-\text{SH}$, $\text{C}_6\text{H}_5\text{C}\equiv\text{NS}$ (benzonitrile-sulfide), $\text{C}_6\text{H}_5\text{PS}_2$, $\text{C}_6\text{H}_5\text{S}-\text{P}=\text{S}$
Organometallic species	$\text{Fe}(\text{O}_2)$ (peroxide), OFeO (dioxide), $\text{Fe}(\text{CO})$, $\text{Fe}(\text{C}_2\text{H}_4)$, $\text{C}_5\text{H}_5-\text{Fe}-\text{R}$ ($\text{R}=\text{halogen}, \text{O}, \text{OH}, \text{OCH}_3, \text{C}_6\text{H}_5, \text{H}$), $\text{C}_5\text{H}_5\text{FeC}_5\text{H}_4=\text{X}$ ($\text{X}=\text{O}, \text{CH}_2, \text{CO}$), SiNH_2^* , Si_2O_2 , Si_3N , $\text{D}_2\text{Si}=\text{CH}_2$ (silaethene), SiC_nH^* ($n=4,6$) (silicon carbon hydrides), $(\text{CH}_3)_3\text{SiC}^*=\text{CH}_2$, $(\text{CH}_3)_3\text{SiCH}=\text{CH}^*$, PrF_n ($n=1-2$), $(\text{C}_5\text{H}_5)_2\text{Zr}$ (zirconocene), $\text{F}_3\text{CCSeNSeCCF}_3^*$

primarily lead to C_3H_5^+ , C_3H_3^+ , and C_2H_5^+ and C_2H_3^+ ; most likely, these products arise from elimination of CH_2O or $\text{C}_2\text{H}_4\text{O}$ (inductive cleavages), followed by one or more dehydrogenations. (c) The fragments generated from the radical $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^*$ are revealed by the positive signals in Figure 10c. Among them are the α -cleavage products $\text{C}_3\text{H}_7^* + \text{CH}_2\text{O}$ (weak); the intramolecular hydrogen transfer products $\text{C}_3\text{H}_6 + \bullet\text{CH}_2\text{OH}$; as well as the product of H_2O loss which indicates the occurrence of a double hydrogen transfer to oxygen. Repeating these experiments with $\text{CD}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^*$ reveals that the intramolecular H-rearrangement involves

a 1,5-hydrogen migration (Scheme 4), similar to the Barton reaction observed in solution. On the other hand, the water elimination from $\text{CD}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^*$ is found to proceed with partial H/D scrambling, leading to the losses of H_2O , HDO , and D_2O in the ratio 1:10:5.

Reactive Neutrals Investigated and Outlook

The basic NRMS method and the auxiliary techniques outlined have enabled the discovery and characterization

of a large variety of reactive neutrals that had eluded experimental studies due to their unusual structures and reactivities. A wide range of species has been studied and many important examples are summarized in **Table 1** and include radicals, diradicals, carbenes, nitrenes, cumulenes, ylides, hypervalent species, and weak intermolecular complexes.

NRMS has primarily been a qualitative method. It determines whether a reactive neutral species is bound and to what it rearranges or dissociates, but it does not easily yield *quantitative* insight about bond dissociation energies and isomerization barriers or about the thermochemistry of the neutral under study; these data have generally been obtained by parallel theoretical calculations. NRMS also does not allow the assessment of the *bimolecular* reactivity of neutral intermediates, which is of paramount interest in organic and biological chemistry and in catalysis. However, in light of the new knowledge NRMS has yielded in less than two decades thus far (**Table 1**), the shortcomings mentioned provide the motivation for future efforts to overcome them.

Symbols

C_x	a constant
d	d -spacing
d_{hkl}	interlayer spacing between crystal planes
$(d\sigma/d\Omega)_{\text{tot}}$	differential cross-section for total neutron diffraction
E	neutron energy
E_f	neutron energy after scattering (final)
E_i	neutron energy before scattering (initial)
h	Planck's constant
$\hbar$	Planck's constant divided by 2π
k_B	Boltzmann's constant
k_f	neutron wavevector after scattering (final)
k_i	neutron wavevector before scattering (initial)
L	total flight path of neutron
L_f	flight path of neutron after scattering (final)
L_i	flight path of neutron before scattering (initial)
m_n	neutron mass
N	number of atoms in sample
n_v	atomic number density
Q	magnitude of momentum transfer
$\mathbf{Q}$	momentum transfer vector
R_{tot}	rate at which neutrons are scattered into the specified solid angle
t	time-of-flight of neutron
T	temperature
v	neutron speed
x	detector thickness
α_i	diffractometer parameter
Δd	resolution uncertainty for d -spacing, d
ΔQ	resolution uncertainty for momentum transfer, Q
$\Delta\theta$	resolution uncertainty for semi-scattering angle, θ
$\Delta\lambda$	resolution uncertainty for neutron wavelength, λ
ε	output pulse fraction for detector
2θ	scattering angle
λ	neutron wavelength

$\sigma_{\text{abs}}(\lambda)$	neutron absorption cross-section at neutron wavelength, λ
σ_{abs}^0	neutron absorption cross-section at neutron wavelength of 1 Ångström
τ	reciprocal lattice vector of crystal
τ	exponential decay time
τ_0	period of the pulsed source
ϕ	polar coordinate
Φ	neutron flux
Ω	solid angle

Neutron diffraction is a very powerful technique for investigating the structure of condensed matter. Crystal structures can be studied, either by diffraction from a polycrystalline powder or from a single crystal sample. Neutron diffraction is also a very important tool for the study of the structure of non-crystalline forms of matter, such as liquids and glasses. This article considers in detail the instrumentation for studying isotropic samples, either polycrystalline powders or non-crystalline materials. Neutrons may be obtained either from a nuclear reactor or from an accelerator-based source. They may be detected using either gas detectors or scintillator detectors. Typical neutron diffractometers at both reactor and accelerator-based sources are described, and a consideration of the resolution is given in each case.

The Neutron

The neutron was discovered by Chadwick in 1932. It is a neutral subatomic particle which has a finite mass, $m_n = 1.0087$ amu, similar to that of the proton. It has a spin of $\frac{1}{2}$ and a magnetic moment of -1.9132 nuclear magnetons. A neutron with speed v has a de Broglie wavelength given by

$$\lambda = \frac{h}{m_n v} \quad [1]$$

and thus the neutron exhibits wavelike behaviour including diffraction.

Normally neutrons only exist within the atomic nucleus and hence a nuclear reaction of some sort must be used in order to produce a beam of neutrons for neutron diffraction. Chadwick first produced neutrons by the

interactions in beryllium of alpha particles from the decay of natural polonium. The first experimental demonstrations of the phenomenon of neutron diffraction were performed in 1936 and these also used radioactive sources. However, the neutron flux available from the decay of a radioactive source is very weak, and since neutron scattering is an intensity-limited technique, all neutron diffraction experiments soon came to be performed using neutrons produced by either a nuclear reactor or an accelerator-based neutron source, both of which produce a much greater flux. The properties of the neutron source have important consequences both for the way in which a neutron diffraction experiment is performed, and for the results obtained, and hence it is worthwhile to discuss below the two important types of neutron source.

Neutron Sources

Reactor Sources of Neutrons

Conventionally, from the 1940s onwards, neutron diffraction experiments were performed using a beam of neutrons derived from a nuclear reactor in which the neutrons are produced by the fission of ^{235}U nuclei. The cross-section for neutron-induced fission of ^{235}U is only high for slow neutrons with energies in the meV range, whereas the fast neutrons produced by fission have high energies in the MeV range. Hence, in order to sustain the fission process, a reactor includes a component, known as a moderator, which slows down the neutrons. The neutrons undergo inelastic collisions with the nuclei in the moderator so that they are in thermal equilibrium at the temperature of the moderator. The moderator normally contains large numbers of low mass nuclei (usually H or D) because the energy transferred in the inelastic collisions is maximized when the mass of the colliding nucleus is as close as possible to the neutron mass. The peak flux within the moderator is at a neutron speed v_p given by

$$\frac{1}{2}m_n v_p^2 = k_B T \quad [2]$$

where T is the temperature of the moderator. For example, a temperature of 290 K corresponds to a neutron energy E of 25 meV, a neutron wavelength λ of 1.8 Å (0.18 nm), or a neutron speed v of 2200 m s⁻¹. In order to perform a neutron diffraction experiment to study the atomic structure of condensed matter it is necessary to use neutrons whose wavelength is of a similar order of magnitude to the interatomic separations in materials. It is thus fortuitous that the process of moderation produces neutrons which, as well as being slowed down for maintaining the fission reaction, also have a wavelength suitable for performing neutron diffraction experiments.

Figure 1 The neutron flux distribution for three different moderators at the ILL reactor and for the liquid hydrogen moderator at the ISIS accelerator. The accelerator flux distribution is adjusted by a factor 10^3 to represent the increased efficiency for time-of-flight experiments due to the pulse structure. Modified with permission from Price DL and Sköld K (1986) *Introduction to neutron scattering*. In: *Neutron Scattering, Part A*, Sköld K and Price DL (eds.). Orlando: Academic Press.

A neutron diffractometer uses a beam of neutrons which is obtained by viewing a moderator through a beam-tube or neutron guide which passes through the shielding around the neutron source. Note that, in practice, the moderator used as a source of neutrons for neutron diffraction experiments at a reactor may be separate from the moderator used to slow the neutrons in order to maintain the fission reaction. **Figure 1** shows the neutron flux for three different moderators at the world's preeminent reactor source of neutrons, the Institut Laue-Langevin (ILL) in Grenoble, France (see **Figure 2**). Reactor neutron sources produce a high flux of thermal neutrons ($E \sim 25$ meV, $T \sim 290$ K) and cold neutrons ($E \sim 1$ meV, $T \sim 12$ K), but they have little flux at higher epithermal energies ($E \sim 1$ eV, $T \sim 12000$ K). This is a consequence of the fact that a reactor can only produce neutrons which are in thermal equilibrium with a moderator and there are practical limitations on the maximum temperature of the moderator.

The neutron flux produced by a normal nuclear reactor is unchanging with time and covers a wide range of neutron wavelengths. In order to perform a neutron diffraction experiment it is thus necessary to monochromate the neutron beam from a reactor so that it covers a narrow

Figure 2 The layout of the reactor and the neutron scattering instrumentation at the ILL reactor. Courtesy of H. Büttner.

range of neutron wavelengths and the vast majority of the flux from the source is lost at this stage.

Accelerator-Based Sources of Neutrons

In more recent years neutron diffraction experiments have increasingly come to be performed using sources of neutrons which are based on a particle accelerator. A beam of charged particles is accelerated to a high energy and then fired at a target. Interactions between the particle beam and the nuclei in the target produce high energy neutrons which are then slowed down by a moderator.

The earlier accelerator-based neutron sources from the 1960s and 1970s use an electron linac to accelerate an electron beam to relativistic energies (~ 50 MeV). The electron beam is fired at a dense target made of a heavy element, usually uranium, and neutrons are produced by a two-stage process. First, the electrons are slowed down extremely rapidly due to the strong interaction with the electromagnetic field of the target nuclei, producing a cascade of bremsstrahlung photons. Secondly, some of these photons go on to produce neutrons by photon-neutron reactions where the photon excites a target

nucleus which subsequently decays with the emission of a neutron. About twenty electrons must be accelerated for each neutron produced.

More recent accelerator-based neutron sources use a linear accelerator, usually together with a synchrotron, to accelerate a beam of protons to a high energy (~ 800 MeV). The proton beam is fired at a heavy metal target (made, for example, of tantalum, uranium or tungsten) and neutrons are produced by the spallation process. Spallation is a violent interaction between the proton and the target nucleus which results primarily in the emission of neutrons, but also a variety of light nuclear fragments. In effect, the protons chip pieces off the target nuclei and each proton produces of the order of fifteen neutrons for a nonfissile target (or about twenty-five neutrons for a fissile target).

Accelerator-based sources are usually pulsed (typically with a pulse repetition rate of the order of 50 Hz) and so they produce a pulsed neutron flux which is ideally suited to the time-of-flight neutron diffraction technique. (Accelerator-based neutron sources which are quasi-steady-state or intensity-modulated also exist. Furthermore, pulsed neutrons have also been produced in Russia by using a pulsed reactor.) This technique

Figure 3 The layout of the neutron source and the neutron scattering instrumentation at the ISIS spallation neutron facility.

involves measuring the time-of-flight, t , taken for a neutron to travel the total flight path, L , from the moderator to the detector, via the sample. On the assumption of elastic scattering (i.e. initial and final neutron energies are the same, $E_i = E_f$) then

$$t = \frac{m_n}{b} L \lambda \quad [3]$$

(or $t = 252.82 L \lambda$ in convenient units of μs , metres and Ångströms, respectively) and it is thus straightforward to determine the neutron wavelength. The use of the time-of-flight technique removes the need to monochromate the neutron beam and thus, even though the raw flux produced initially by an accelerator-based source is much less than that produced by a reactor source, the final flux available for neutron diffraction is of a comparable order of magnitude (see **Figure 1**).

The moderator at an accelerator-based neutron source is used to slow the neutrons down so that they have suitable wavelengths for neutron diffraction, in the same way as for a reactor neutron source. However, in order that the moderation process does not broaden the pulsed time structure of the neutron flux too much, the moderator must be relatively small. (Also note that, unlike a reactor, the process of moderation plays no role in

the production of neutrons at an accelerator-based source.) This has the consequence that the neutrons produced by an accelerator-based source are under-moderated and there are many more epithermal neutrons than for a reactor source. **Figure 1** also shows the neutron flux for a moderator at the world's most intense pulsed neutron source, the ISIS spallation neutron source at the Rutherford Appleton Laboratory, UK (see **Figure 3**).

Neutron Detectors

The single most important component of a neutron diffractometer is the detector array. The lack of a charge on the neutron means that it cannot directly create an electrical signal in a detector. Instead the neutron must be made to undergo a nuclear reaction which subsequently leads to an electrical signal.

The three most important reactions for neutron detection involve the ^3He , ^{10}B and ^6Li nuclei:

Generally, the efficiency of detection of neutrons of wavelength, λ , by a detector of thickness x , containing a number density, n_a , of absorbing atoms with neutron absorption cross-section, $\sigma_{\text{abs}}(\lambda)$, may be expressed as

$$\text{Efficiency} = \varepsilon(1 - \exp(-n_a x \sigma_{\text{abs}}(\lambda))) \quad [5]$$

where ε is the fraction of absorption events which result in an output pulse from the detector. Usually the absorption cross-section used in detection is proportional to the neutron wavelength (a so-called $1/v$ cross section):

$$\sigma_{\text{abs}}(\lambda) = \lambda \sigma_{\text{abs}}^0 \quad [6]$$

where σ_{abs}^0 is a constant. For good performance the ideal neutron detector should have a high neutron detection efficiency, a low intrinsic detector background, a low sensitivity to non-neutron events (particularly gamma rays), a good stability and a short dead-time.

Gas Detectors

A simple gas detector consists of a sealed metal tube, which contains either ^3He or BF_3 gas under pressure (typically 10 bar; 10^6 Pa), with a high voltage thin wire anode along its axis (see **Figure 4a**). When a neutron is absorbed (eqn [4]) the energetic recoil particles produce ionization in the gas. The anode then collects electrons from the ionization and an electrical signal is produced.

Figure 4 Schematic of (a) a gas detector and (b) a scintillator detector (modified with permission from Windsor CG (1981) *Pulsed Neutron Scattering*. London: Taylor and Francis).

Although BF_3 is cheaper than ^3He , it is little used now because it is less efficient and the gas is toxic. An advantage of using ^3He gas is that it is self-regenerating because the triton produced when a neutron is absorbed undergoes beta decay with a half-life of 12.33 years to produce another ^3He nucleus:

Gas detectors have a pulse height distribution in which the signal due to gamma rays is well separated from the neutron signal. Hence, the detector electronics can be made to discriminate very well against gamma rays, leading to a very low gamma ray sensitivity ($\sim 10^{-8}$ at 1 MeV). Furthermore, gas detectors have a very low intrinsic detector background (at best ~ 3 –5 counts per hour) and a good stability. In practice, modern neutron diffractometers often use multiwire detectors, where a large number of anodes are contained within a single envelope, in order to cover a larger solid angle and hence obtain a higher count rate. Also resistive-wire position-sensitive detectors are sometimes used for applications where it is useful to be able to determine the position along the length of the detector where a neutron is detected.

Gas detectors are relatively expensive and it is difficult to make the active element take up more complex geometries and shapes. Furthermore, it is difficult to make the active elements small, which is advantageous for good diffractometer resolution.

The most recent development in gas detector technology to be applied is the microstrip detector. In a microstrip detector the metal anode is replaced by a semiconducting glass plate on which very thin metallic strips are engraved by photolithographic means. In this way, the limitations on the size and shape of gas detector elements may be overcome in the future.

Scintillator Detectors

The aim with a scintillator detector is to combine the neutron absorbing element intimately with a scintillating phosphor so that the reaction products from the capture of a neutron strike the phosphor and produce a light flash, which is then detected by a photomultiplier tube (see **Figure 4b**).

There are two types of scintillator material in common use for neutron detection: $^6\text{Li}/\text{Ce}$ glass scintillator and granular $\text{ZnS}(\text{Ag})/^6\text{Li}$ scintillator. **Figure 5** illustrates the physical principles behind the operation of an ideal scintillator material. The absorption of a neutron by a ^6Li nucleus causes a large amount of energy to be deposited in the scintillator material, resulting in the excitation of electrons from the valence band into the conduction band. An excited electron can bind together

with a hole to form an exciton which propagates through the lattice. When the exciton reaches an impurity activator atom (Ce for the glass scintillator, or Ag for the ZnS scintillator) it becomes trapped and then it recombines to emit a flash of light. Since the activator atoms have levels within the band gap of the scintillator material, the photon emitted has an energy less than the band gap and can pass through the material without absorption.

The earlier scintillator detectors used at ISIS were based on the lithium glass material. Such detectors have a high neutron detection efficiency (comparable to or even exceeding that of a gas detector), but also a very high gamma sensitivity (0.02 at 1 MeV), a large intrinsic detector background (~ 150 counts per minute) and a poor stability. Thus, neutron diffraction results obtained using lithium glass scintillator detectors can suffer from background and absolute normalization problems. More recent scintillator detectors are almost always based on ZnS. This gives a high neutron detection efficiency

(comparable to, or even exceeding, that of a gas detector), a low gamma sensitivity (at best $\sim 10^{-8}$ at 1 MeV), a low intrinsic detector background (at best ~ 12 counts per hour) and a much improved stability.

One of the advantages of scintillator detectors is that a high efficiency can be obtained in a small thickness of material because a higher density of absorbing atoms can be achieved than is possible with a gas detector (cf. eqn [5]). This can be of particular importance for achieving a large efficiency for the detection of higher energy neutrons, for which the absorption cross-section is relatively small (cf. eqn [6]). Another advantage of scintillator detectors is that a high degree of flexibility can be achieved in terms of the size and geometry of the active component. For example, this allows the detectors to be designed to be narrow and to follow the Debye–Scherrer cone so that the resolution width for the diffractometer is minimized.

Neutron Diffraction Instrumentation

Instrumentation – General Principles

The purpose of a total neutron diffractometer is to measure the differential cross-section

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{tot}} = \frac{R_{\text{tot}}}{N\Phi d\Omega} \quad [8]$$

where R_{tot} is the rate at which neutrons of wavelength λ are scattered into the solid angle $d\Omega$ in the direction $(2\theta, \phi)$ (see **Figure 6**), regardless of whether or not they are scattered elastically (i.e. total diffraction). N is the number of atoms in the sample and Φ is the flux of neutrons of wavelength λ which is incident on the sample.

Figure 5 The physical principles behind the operation of a scintillator material. Reproduced with permission from Bennington SM, Hannon AC, and Forsyth JB (1993) *Rutherford Appleton Laboratory Report RAL-93-083*.

Figure 6 The geometry for a neutron diffraction experiment.

In general, the differential cross-section depends upon the scattering vector

$$\mathbf{Q} = \mathbf{k}_i - \mathbf{k}_f \quad [9]$$

where $\mathbf{k}_i$ and $\mathbf{k}_f$ are the neutron wave vector before and after scattering. The term momentum transfer (i.e. the momentum transferred to the sample) is commonly used for $\mathbf{Q}$, although strictly speaking this term should be used for $\hbar\mathbf{Q}$. Diffraction data may be treated by considering the scattering to be totally elastic so that the magnitudes of the initial and final neutron wave vectors are the same,

$$|\mathbf{k}_i| = |\mathbf{k}_f| \quad [10]$$

The most frequently used type of neutron diffraction involves the study of the atomic structure of isotropic samples (polycrystalline powders, glasses, liquids, etc.) and hence this article gives greatest emphasis to the instrumentation for this type of experiment. For an isotropic sample, it is only the magnitude of the momentum transfer which is important (the direction is not important), and in this case the differential cross section is a function of a single variable

$$Q = |\mathbf{Q}| = \frac{4\pi \sin \theta}{\lambda} \quad [11]$$

For neutron diffraction experiments on polycrystalline powders it is usually more convenient to treat the differential cross section as a function of d -spacing, d ($= 2\pi/Q$), defined according to Bragg's law by

$$2d \sin \theta = \lambda \quad [12]$$

Bragg peaks are then observed in the differential cross section whenever the d -spacing satisfies

$$d = d_{hkl} \quad [13]$$

where d_{hkl} is a d -spacing between atomic planes in the crystal for which the structure factor is non-zero.

In order to produce high quality data, a neutron diffractometer must satisfy several requirements: The data must have a good statistical accuracy, which is obtained by having a high count rate. This is achieved by such factors as a bright source and a large total detector solid angle. The corrections which must be made to the data must be small. In particular, the background must be small, featureless and unchanging. The range in Q must be as wide as possible, in order to provide high resolution in real-space. The reciprocal-space resolution must be as narrow as possible (see below).

Reactor Source Instrumentation

Figure 7 shows a schematic of the layout of a typical neutron diffractometer at a reactor source. The neutron beam coming from the moderator at a reactor covers a wide range of wavelengths and is unchanging with time. It is thus necessary to use a single crystal monochromator so as to produce a monochromatic beam. The general principle of operation of a neutron diffractometer at a steady state source is the same as for a conventional X-ray diffractometer. The differential cross-section is measured as a function of Q by moving the detector to different scattering angles, 2θ , and measuring the scattered count rate. That is to say, Q (or d) is scanned by varying 2θ whilst keeping the neutron wavelength λ constant (cf. eqn [11]).

Figure 8 shows the D4 diffractometer at the ILL reactor which, for many years, has been the most successful reactor-based diffractometer for studying the structure of liquids and amorphous materials. The diffractometer uses neutrons from a hot graphite moderator at a temperature of 2400 K because this produces neutrons with short wavelengths and hence a high maximum Q can be achieved, leading to good real-space resolution. A copper monochromator is used to produce neutrons with a wavelength of 0.7 Å, 0.5 Å or 0.35 Å, depending upon which copper reflection is selected. Most of the neutron flight path is evacuated in order to minimize background due to the scattering of neutrons by air. Two 64-wire ^3He gas multidetectors are used in order to provide a large detector solid angle and hence a high count rate. The multidetectors are moved on compressed air across a marble floor in order to cover the full range of scattering angles. With a wavelength of 0.5 Å the Q -range of D4 extends from 0.3 to 24 Å⁻¹. (A higher maximum Q may be attained at $\lambda = 0.35$ Å, but the flux available at this wavelength is too low for regular use.) Enhancements include the replacement of the multidetectors with microstrip detectors, increasing the count rate by an order of magnitude.

Figure 7 Schematic of a neutron diffractometer for a steady-state (reactor) source.

(1989) A neutron-diffraction and molecular-dynamics investigation of the environment of Dy^{3+} ions in a fluoroberyllate glass. *Journal of Chemical Physics* 91: 6380–6392.

Pulsed Source Instrumentation

Figure 9 shows a schematic of the layout of a typical neutron diffractometer at a pulsed neutron source. The time-of-flight technique (see eqn [3]) is used to determine the wavelength of the detected neutrons and hence a monochromator is not needed. The differential cross-section is measured as a function of Q with the detector at a fixed scattering angle, 2θ , and Q (or d) is scanned by varying the neutron wavelength λ (cf. eqn [11]). The time-of-flight technique is thus a dispersive technique and a white beam covering a wide range of wavelengths is incident on the sample. For powder diffraction, pulsed source data have the simplifying property that time-of-flight is proportional to d -spacing:

$$t = \frac{2m_n}{h} Ld \sin \theta \quad [14]$$

(or $t = 505.64 Ld \sin \theta$ in convenient units of μs , metres and Ångströms, respectively).

A noteworthy advantage of the ability to measure a full diffraction pattern at a single fixed scattering angle is that complex sample environment equipment can be used (e.g. for high pressures) with two well-collimated flight paths for the incident and scattered beams so that background from the equipment is minimized.

In the analysis of data from a pulsed source diffractometer, it is necessary to normalize out the flux distribution $\Phi(\lambda)$ arising from the moderator. This is done by measuring the time-of-flight spectrum for a vanadium

Figure 9 Schematic of a neutron diffractometer for a pulsed (accelerator-based) source.

standard, as well as for the sample. Vanadium is used for this purpose because the scattering from vanadium is almost completely incoherent and the Bragg peaks are extremely small (nevertheless, it is necessary to remove the Bragg peaks from the data by some kind of smoothing process). In practice, the differential cross-section for the sample is determined by performing the following operation with the measured time-of-flight spectra:

$$\text{Normalized sample spectrum} = \frac{(\text{sample} - \text{empty container background})}{(\text{vanadium} - \text{background})} \quad [15]$$

(A fully corrected dataset will also have been corrected for such effects as detector dead-time, attenuation and multiple scattering.) Figure 10 illustrates the effect of flux normalization for pulsed diffraction data, using data

Figure 10 Time-of-flight spectra for (a) vanadium, (b) polycrystalline silicon and (c) vitreous germania. Also shown are the normalized spectra for (d) polycrystalline silicon and (e) vitreous germania.

from the LAD diffractometer described below. The vanadium time-of-flight spectrum is closely related to the flux distribution $\Phi(\lambda)$ arising from the moderator. The upturn in $\Phi(\lambda)$ at short times is due to high energy epithermal neutrons whilst the broad peak at intermediate times is the peak of a Maxwellian distribution whose position depends on the moderator temperature (cf. eqn [2]). The spectra measured on a reactor diffractometer do not need to be normalized to a flux distribution, but a vanadium standard may still be used in an experiment in order to achieve an absolute normalization of the differential cross section.

Figure 11 shows the LAD (liquids and amorphous diffractometer) instrument at the ISIS spallation neutron source. LAD has been the main ISIS diffractometer for the study of disordered materials since the start of operations at ISIS and its design is typical for an early pulsed source diffractometer. The neutron beam comes from a liquid methane moderator at a temperature of 110 K. A cooled moderator is used in order to reduce the correction for inelasticity effects. The incident flight path, L_i , is 10.0 m long, leading to a moderately high reciprocal-space resolution. In practice, a pulsed source diffractometer has several different detector banks at different scattering angles so as to extend the Q -range of the data. LAD has detector banks at seven different scattering angles, some of which use ^3He gas detectors, whilst the others use lithium glass scintillator detectors. The detectors are all in the horizontal plane. In order to minimize background there are large amounts of

shielding between the detector banks. Thus the solid angle subtended by the relatively low detector area is small and hence the count rate of the instrument is not very high. The best resolution is obtained in the backward angle detectors ($2\theta = 150^\circ$) with $\Delta Q/Q \sim 0.5\text{--}0.6\%$.

Figure 12 shows the GEM (general materials) diffractometer at ISIS which is being constructed to replace the LAD diffractometer. This will be a state-of-the-art pulsed source diffractometer to be used for both non-crystalline diffraction and powder crystallography. The incident flight path, L_i , will be relatively long at 17.0 m, giving a very small flight path contribution to the resolution. Thus the resolution in the backward angle detectors will be very good with $\Delta Q/Q \sim 0.2\text{--}0.3\%$. All of the detectors will be ZnS scintillators using narrow 5 mm active elements in order to minimize the angular contribution to the resolution. The detectors will cover a very large solid angle (area $\sim 10\text{ m}^2$, maximum azimuthal angle $\sim 45^\circ$) so as to achieve a high effective count rate. A nimonic t_0 chopper at a distance 9.3 m from the moderator will be used to close off the beam at $t = 0$ and thus prevent very fast neutrons and prompt gamma rays from reaching the sample. This will prevent high energy neutrons from thermalizing in large pieces of sample environment equipment (e.g. high pressure) and then giving rise to a substantial background. In addition, two disc choppers will be used at flight paths of 6.5 m and 9.5 m to define a restricted wavelength range for the beam reaching the sample. This will be done so as to avoid frame overlap, which can be a significant problem for a

Figure 11 The LAD diffractometer at the ISIS spallation neutron source.

Figure 12 The new GEM diffractometer at the ISIS spallation neutron source.

diffractometer with a longer flight path. Frame overlap occurs when slower neutrons from a pulse of the source are overtaken by faster neutrons from the subsequent pulse. If the flux of the slower neutrons is significant, then a diffraction peak, which in reality is detected at the long time-of-flight, t , appears to be detected at the earlier time, $t - \tau_0$ (where τ_0 is the period of the source), and this leads to spurious peaks in the data.

Reciprocal-Space Resolution

A certain point in a diffraction pattern picks out the scattering at some momentum transfer Q . However, this Q is never completely defined due to uncertainties in the

various parameters α_i of the diffractometer used to determine Q , leading to an overall uncertainty ΔQ . In practice the parameters α_i may be highly dependent, but for a simple discussion of Q -resolution it may be assumed that the parameters all act independently so that

$$\Delta Q = \left[\sum_i \left(\frac{\partial Q}{\partial \alpha_i} \Delta \alpha_i \right)^2 \right]^{1/2} \quad [16]$$

The parameters which are important in determining the resolution will depend on the details of the particular diffractometer being used and thus only an outline of some of the general principles and dependencies for diffraction from an isotropic sample can be given here.

Resolution of a Reactor Diffractometer

For a reactor diffractometer the resolution width, ΔQ , arises because the acceptance angle of the collimation around the monochromator, the size of the sample and the acceptance angle of the detector system are all greater than zero and also because the monochromator crystal has a mosaic spread. For a treatment of the Q -resolution in terms of independent parameters, these factors may be considered to lead to a geometrical uncertainty in angle, $\Delta\theta$, and an uncertainty in wavelength, $\Delta\lambda$. Differentiating the definition of Q (eqn [11]) thus gives

$$\frac{\Delta Q}{Q} = \frac{\Delta d}{d} = \left[(\cot\theta \Delta\theta)^2 + \left(\frac{\Delta\lambda}{\lambda} \right)^2 \right]^{1/2} \quad [17]$$

where the semi-angle, θ , is in radians, not degrees.

Figure 13 shows the experimental Q -resolution of the D4 reactor diffractometer (measured at $\lambda = 0.7$ Å for powder samples of YIG, Si, Ni and Fe with diameter 7 mm and height 45 mm, and with the detector at 1.455 m). For the range of angle shown, $Q\cot\theta$ changes little and hence the Q -resolution may be expressed approximately as

$$\Delta Q = (C_\theta + C_\lambda Q^2)^{1/2} \quad [18]$$

where C_θ and C_λ are constants. This simple independent-parameter expression predicts the general trend of Figure 13. However, the detailed behaviour, and in particular the upturn in ΔQ at low Q , is not predicted, and a full analysis of the Q -resolution must treat the parameters as being dependent.

The resolution of a reactor diffractometer may be improved by reducing the uncertainties in angle and wavelength. However, this can only be achieved at the

Figure 13 The measured experimental resolution (full width at half maximum) of the D4 reactor diffractometer. Courtesy of HE Fischer.

expense of a corresponding decrease in the count rate of the diffractometer. For non-crystalline samples the Q -resolution is of less importance than for polycrystalline samples because the diffraction peaks are relatively broad (cf. Figure 10). The D4 diffractometer is used mainly to study non-crystalline samples and hence it has been optimized primarily to have a high count rate. Thus the Q -resolution of D4 is not the best that can be achieved at a reactor neutron source.

Resolution of a Pulsed Source Diffractometer

For a time-of-flight diffractometer the three major contributions to the Q -resolution are due to the geometrical uncertainty in angle, $\Delta\theta$, the uncertainty in flight path, ΔL , and the uncertainty in time-of-flight, Δt , leading to the following expression for the total combined resolution width:

$$\frac{\Delta Q}{Q} = \frac{\Delta d}{d} = \left[(\cot\theta \Delta\theta)^2 + \left(\frac{\Delta L}{L} \right)^2 + \left(\frac{\Delta t}{t} \right)^2 \right]^{1/2} \quad [19]$$

The angular uncertainty for a time-of-flight diffractometer, $\Delta\theta$, is similar to the reactor case in that it arises from the acceptance angle of the collimation in front of the moderator, the size of the sample and the acceptance angle of the detector. However, there is a major difference in its effect because of the way in which a single detector measures a complete diffraction pattern without moving to different scattering angles, 2θ , so that the angular contribution to $\Delta Q/Q$ is independent of Q . This contribution to the resolution is ideally suited to powder diffraction because it has a Δd which is small for short d -spacing where Bragg peaks are very close together, and only becomes large at high d -spacing where Bragg peaks are well separated.

The flight path uncertainty, ΔL , arises from the finite sizes of the moderator, sample and detector. Its contribution to the resolution is symmetric and may be approximated by a Gaussian, as is also the case for the angular contribution. The contribution to $\Delta d/d$ due to the flight path uncertainty may be minimized simply by using a very long flight path, L , although this may only be achieved at the expense of a corresponding decrease in the count rate.

At low and medium scattering angles, $\cot\theta$ is relatively large and the angular contribution to the resolution tends to dominate. However, at backward angles ($2\theta \rightarrow 180^\circ$) this contribution becomes very small so that a diffraction pattern can be measured with a very narrow angular resolution across its entire range. The time-of-flight uncertainty, Δt , is then of greater importance. Its main component is the time uncertainty which arises from the moderation process. This gives an exponential contribution

to the resolution with a decay time, τ , which is the mean time spent in the moderator for neutrons of a particular wavelength. **Figure 14** shows the resolution of the LAD time-of-flight diffractometer at backward angle, obtained by fitting the convolution of a Gaussian and an exponential to Bragg peaks in experimental data. The Gaussian contribution to $\Delta d/d$ is almost independent of d -spacing, as predicted. The detailed behaviour of the decay time, τ , depends upon the design of the moderator, but is generally small at short times (i.e. for high energy neutrons) and tends to a large value at long times (i.e. for low energy neutrons). The overall peak shape, Gaussian-exponential convolution (see inset to **Figure 14**), has a very sharp

Figure 14 The measured experimental resolution of the LAD pulsed neutron diffractometer at backward angle, $2\theta = 146^\circ$. The total full width at half maximum (FWHM) and the FWHM for the Gaussian contribution are shown in the form of $\Delta d/d$. Also shown is the decay constant τ for the exponential contribution to the resolution. The inset shows the peak shape measured for a typical Bragg peak (the (331) reflection for polycrystalline silicon).

leading edge which can be advantageous in resolving overlapping peaks.

Some Other Types of Neutron Diffraction Instrumentation

In this article the greatest emphasis is given to wide angle neutron diffraction from isotropic samples. However, a range of other neutron diffraction techniques is also available and it is only possible to describe some of them briefly here. (One of the major advantages of neutrons is that polarized beams can be used and these are especially useful for the study of magnetic structures. However, a discussion of polarized neutron diffraction instrumentation is beyond the scope of this article.)

Small Angle Neutron Scattering at a Reactor

A small angle neutron scattering (SANS) diffractometer is used to study structures whose dimensions range from 10 to 1000 Å (e.g. defects, voids, micelles, macromolecules, etc.) and as such their Q -ranges are in the region of 0.005 to $0.5 \text{ \AA}^{-1}$. In order to access these low values of Q the detector should be at low scattering angle, 2θ , and a cold moderator should be used so as to provide long wavelength neutrons (cf. eqn [11]).

Figure 15 shows a schematic of the layout of a typical small angle neutron scattering (SANS) diffractometer at a reactor source. A large two-dimensional multiwire area detector is placed at a low angle so as to cover as large a solid angle as possible and thus maximize the count rate. The detector is either placed symmetrically around the transmitted beam (as shown in **Figure 15**) to maximize the count rate for the lowest Q or placed off-axis to extend the Q -range upwards. The neutron beam is monochromated by a velocity selector which consists of a rotating cylinder with a set of helical grooves cut into its outer surface. The angular contribution to the resolution is unavoidably large at low angle because $\cot \theta$ becomes large (cf. eqn [17]). Hence the monochromation produced by the velocity selector is relatively coarse ($\Delta\lambda/\lambda \sim 5\text{--}20\%$) so as to match the angular contribution and provide as large an incident flux as possible. The D11 diffractometer at the ILL is a prime example of a reactor SANS instrument.

Figure 15 Schematic of a small angle neutron scattering (SANS) diffractometer for a steady-state (reactor) source.

Figure 16 Schematic of a single crystal diffractometer on a pulsed (accelerator-based) source.

Single Crystal Diffraction at a Pulsed Source

In an experiment on a single crystal sample the differential cross-section must be measured as a function of the magnitude and the direction of the momentum transfer vector, $\mathbf{Q}$. Bragg peaks are then observed in the differential cross-section whenever $\mathbf{Q}$ satisfies

$$\mathbf{Q} = \boldsymbol{\tau} \quad [20]$$

where $\boldsymbol{\tau}$ is a reciprocal lattice vector of the crystal.

Figure 16 shows a schematic of the layout of a typical pulsed source single crystal diffractometer. A goniometer is used to provide full control of the orientation of the sample in space so that any region of reciprocal-space of interest can be studied. An area detector combined with the use of multiwavelength data provides a three-dimensional sampling of reciprocal-space that may contain hundreds of Bragg reflections. This wide sampling for a pulsed source diffractometer is advantageous

because it may reveal unexpected Bragg reflections or satellites and can show diffuse scattering between the Bragg peaks. The SXD diffractometer at ISIS is a prime example of a pulsed source single crystal diffractometer.

Symbols

a	lattice parameter
a^*	reciprocal lattice vector
b	lattice parameter
b^*	reciprocal lattice vector
b_j	(bound atom) neutron scattering length for nucleus j
$\bar{b}_l$	coherent scattering length for element l
$\overline{b_l^2}$	mean square scattering length for element l
$\langle \bar{b}^2 \rangle_{av}$	average value of $\bar{b}^2$ for a sample
$\langle \overline{b^2} \rangle_{av}$	average value of $\overline{b^2}$ for a sample
c	lattice parameter
c^*	reciprocal lattice vector
c_l	atomic fraction for element l
d_{hkl}	d -spacing
dS	elemental area
$d^2\sigma/dE$	double differential cross-section
$d\sigma/d\Omega$	differential cross-section
E_i	energy of neutrons in incident monochromatic beam
E_f	energy of neutron after scattering
E	energy transferred from neutron to sample
$F(Q)$	structure factor in crystallography
g^0	average atomic number density
$G_{ }^D(r, t)$	generalized van Hove distinct correlation function
h	index of Bragg reflection
$i(Q)$	distinct scattering
I	nuclear spin
$I(Q)$	differential cross-section for total diffraction
k	index of Bragg reflection
k	neutron wave vector
k_i	wave vector of incident neutron
k_f	wave vector of scattered neutron
l	index of Bragg reflection
m_n	neutron mass
n_{jk}	coordination number
N	number of atoms in sample
N_l	number of atoms of element l in sample
Q	momentum transfer

r	polar coordinate
R_x	the rate at which neutrons are scattered into a given final state
$R_j(t)$	position of j th nucleus at time t
R_d	equilibrium position of d th atom in unit cell
$S(Q)$	structure factor for disordered materials
t	time
T	temperature of sample
$t_{ }(r)$	partial neutron correlation function
$T(r)$	neutron correlation function
$T^0(r)$	average density contribution to neutron correlation function
$\langle u^2 \rangle$	mean square thermal displacement of atom from equilibrium
$\langle u_{jk}^2 \rangle$	mean square thermal variation in interatomic distance
$V(r)$	Fermi pseudo potential
W_d	Debye–Waller factor
$\delta(x)$	Dirac delta function
2θ	scattering angle
λ	neutron wavelength
v_0	volume of unit cell
$\rho_b(r)$	scattering length density
ρ_b^0	average scattering length density
σ_{inc}	incoherent cross-section
τ_{hkl}	reciprocal lattice vector
ϕ	polar coordinate
Φ	flux in incident neutron beam
Ψ_f	wave-function of scattered neutron
Ω	solid angle

The cross-section measured in a neutron scattering experiment on a non-magnetic material depends in general upon a correlation function involving the positions in time and space of the atomic nuclei in the sample. For a total neutron diffraction experiment the diffraction pattern depends upon a correlation function involving the instantaneous interatomic vectors between the nuclei. However, for an elastic diffraction experiment the diffraction pattern depends upon a correlation function involving the time-averaged interatomic vectors between the positions of the nuclei. The correlation function is obtained by performing a suitable Fourier transform of

the diffraction pattern and its features indicate which interatomic distances occur more or less frequently in the sample. The neutron correlation function is thus a powerful tool for the study of the atomic structure of glasses, liquids and disordered crystalline materials. For a crystalline sample the symmetry of the atomic structure gives rise to sharp Bragg peaks in the diffraction pattern involving only elastically scattered neutrons. The positions of the Bragg peaks and their systematic absences depend upon the symmetry of the crystal lattice. Meanwhile the intensities of the Bragg peaks depend upon the positions of the atoms in the unit cell. A single crystal neutron diffraction experiment yields both the symmetry of the lattice and the contents of the unit cell, whilst a powder neutron diffraction experiment is usually only used to reveal the unit cell contents for a crystal whose symmetry is already known.

Fundamental Theory

The Interaction between a Neutron Beam and a Sample

If a sample is placed in a beam of neutrons then some of the neutrons will be removed from the transmitted beam due to scattering. There are two interactions which give rise to this scattering. The first of these is the nuclear force between a neutron and the nuclei of the sample. The second interaction is that between the magnetic moment of the neutron and the unpaired electrons of magnetic ions in the sample. The treatment of magnetic scattering (and polarized neutron scattering) is beyond the scope of this article. (There are two key differences between magnetic and nuclear scattering: magnetic scattering involves a form factor, and it also has a directional dependence (on magnetic moment) which does not arise for nuclear scattering.) The basic properties of the neutron and their consequences for diffraction are summarized in **Table 1**.

Neutron Cross-Sections

Consider a monochromatic beam of neutrons of energy E_i , wave vector k_i and flux Φ which is incident on a sample of N atoms. The scattering of the neutrons may then be defined experimentally by the double differential cross-section:

$$\frac{d^2\sigma}{d\Omega dE} = \frac{R_{\text{inel}}}{N\Phi d\Omega dE} \quad [1]$$

where R_{inel} is the number of neutrons scattered per unit time into the solid angle $d\Omega$ in the direction $(2\theta, \phi)$ (see **Figure 1**) with final energy E_f in the range $E_i - E$ to $E_i - (E + dE)$. The energy $E (= E_i - E_f)$ is that transferred by the neutron to the sample in a given scattering

Table 1 The properties of the neutron-sample interaction and their consequences for diffraction

Property	Consequences
No form factor for scattering	Data can be measured to high momentum transfer, leading to high real-space resolution Absolute normalization of results is relatively straightforward
Scattering length is different for different isotopes	Isotopic substitution can be used to extract element-specific information
Scattering length varies haphazardly across the periodic table	The positions of light atoms (especially hydrogen) can be determined in the presence of heavy atoms The positions of atoms of elements which are close in the periodic table can be distinguished
Interaction is relatively weak	Neutrons are highly penetrating and hence results are characteristic of the bulk of a sample, not the surface Bulky equipment can be used to subject the sample to a wide range of environments
Magnetic interaction between neutron and magnetic ions	Magnetic structures can be determined

event. The double differential cross-section is the fundamental quantity for the scattering of neutrons and the cross-section for a given experimental arrangement (e.g. diffraction or transmission) is obtained from it by performing suitable integration(s).

In a total diffraction experiment all scattered neutrons are detected regardless of their final energy. In this case the relevant cross-section is the differential cross-section defined by

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{tot}} = \frac{R_{\text{tot}}}{N\Phi d\Omega} = \int_{-\infty}^{\infty} \left(\frac{d^2\sigma}{d\Omega dE}\right) dE \quad [2]$$

where R_{tot} is the number of neutrons scattered per unit time into the solid angle $d\Omega$ in the direction $(2\theta, \phi)$. This is to be contrasted with the case of elastic diffraction where only neutrons whose energy is unchanged (i.e. they are scattered elastically and have $E=0$) are detected. In this case the relevant cross-section is

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{el}} = \frac{R_{\text{el}}}{N\Phi d\Omega} = \left.\frac{d^2\sigma}{d\Omega dE}\right|_{E=0} \quad [3]$$

where R_{el} is the number of neutrons scattered elastically per unit time into the solid angle $d\Omega$ in the direction $(2\theta, \phi)$. The elastic differential cross-section is given by evaluating the double differential cross-section at $E=0$.

Figure 1 Geometry for a neutron scattering experiment.

Neutron Scattering Length

To perform a neutron diffraction experiment, the neutron wavelength needs to be of similar magnitude to interatomic distances, say of the order of 1 Ångström ($1 \text{ Å} \equiv 10^{-10} \text{ m}$ – Ångström units are almost universally used in the field of diffraction). This corresponds to a neutron energy of 25 meV, and thus the energies of neutrons used for diffraction are very much lower than typical X-ray energies used in diffraction. Nuclear forces are very short range ($\sim 10^{-15} \text{ m}$), operating over much shorter distances than neutron wavelengths. Hence nuclei can be treated as point-like scattering centres which give rise to an isotropic scattered neutron wave (i.e. only s-wave scattering need be considered). The wavefunction of a neutron scattered by a single nucleus at the origin is thus expressed as

$$\Psi_r = -\frac{b}{r} \exp(ikr) \quad [4]$$

where k is the magnitude of the wave vector for the scattered wave and r is a polar coordinate. b is a constant, known as the (bound atom) scattering length, which has units of length. A positive scattering length corresponds to a phase change of π between the scattered and incident waves. Most scattering lengths are positive, but there is a

minority of cases where the scattering length is negative. The neutron scattering length corresponds to the form factor in X-ray diffraction, but with the important difference that it is a simple constant without any wave vector dependence.

Fermi Pseudo Potential and the General Expression for Cross-Section

The interaction between a neutron and a sample may be represented by the Fermi pseudo potential:

$$V(\mathbf{r}) = \frac{2\pi\hbar^2}{m_n} \sum_{j=1}^N b_j \delta(\mathbf{r} - \mathbf{R}_j) \quad [5]$$

where m_n is the neutron mass, and the summation is taken over the N nuclei whose position vectors and scattering lengths are $\mathbf{R}_j$ and b_j respectively. Use of the Fermi pseudo potential together with Fermi's golden rule (sometimes termed the Born approximation) eventually results in the following general expression from which all results for the nuclear scattering of neutrons may be derived:

$$\frac{d^2\sigma}{d\Omega dE} = \frac{1}{N} \frac{k_f}{k_i} \frac{1}{2\pi\hbar} \sum_{j,j'} b_j b_{j'} \int_{-\infty}^{\infty} \langle \exp\{-i\mathbf{Q} \cdot [\mathbf{R}_j(0) - \mathbf{R}_{j'}(t)]\} \rangle \exp(-iEt/\hbar) dt \quad [6]$$

The summations j and j' are both taken over the N nuclei of the sample and the angular brackets denote a thermal average at the temperature T of the sample. $\mathbf{R}_j(t)$ is the position of the j th nucleus at time t and $\mathbf{Q}$ is the scattering vector, defined by

$$\mathbf{Q} = \mathbf{k}_i - \mathbf{k}_f \quad [7]$$

where $\mathbf{k}_i$ and $\mathbf{k}_f$ are the incident and scattered neutron wave vectors respectively. The term momentum transfer (i.e. the momentum transferred to the sample) is commonly used for $\mathbf{Q}$, although strictly speaking this term should be used for $\hbar\mathbf{Q}$.

Total Diffraction

The Static Approximation

In the static approximation it is assumed that the incident neutron energy E_i is large compared with the excitation energies of the sample. This means that $k_f \approx k_i$ so that the scattering vector may be taken to have its elastic value:

$$Q = |\mathbf{Q}| = 2k \sin \theta = \frac{4\pi \sin \theta}{\lambda} \quad [8]$$

where λ is the wavelength of the neutrons. In the static approximation eqn [6] may be integrated according to eqn [2] to obtain eqn [9]. (In practice the assumptions inherent in the static approximation do not hold exactly and as a consequence an inelasticity correction must be made to experimental total diffraction data.)

$$\left(\frac{d\sigma}{d\Omega} \right)_{\text{tot}} = I(\mathbf{Q}) = \frac{1}{N} \sum_{j,j'} b_j b_{j'} \times \langle \exp \{ -i\mathbf{Q} \cdot [\mathbf{R}_j(0) - \mathbf{R}_{j'}(0)] \} \rangle \quad [9]$$

Thus the total diffraction pattern $I(\mathbf{Q})$ depends upon the vectors $\mathbf{R}_j - \mathbf{R}_{j'}$ between the atoms, with a weighting according to scattering length. This is the basis for the use of total diffraction to measure the atomic structure of a sample. Total diffraction depends upon the positions of the atoms in the sample at an arbitrary time zero. Thus total diffraction yields an instantaneous 'snapshot' of the interatomic vectors.

Coherent and Incoherent Scattering

For a consideration of coherent and incoherent scattering it is convenient to write eqn [9] in the form

$$I(\mathbf{Q}) = \sum_{j,j'} b_j b_{j'} \langle j, j' \rangle \quad [10]$$

The value of b_j is not the same for all the nuclei of a single element, owing to spin and isotopic incoherence, as will be explained below. Hence, to obtain a useful

result, eqn [10] is averaged over all possible distributions of scattering length, making the assumption that there is no correlation between the values of b_j for any two nuclei. Now the average value of $b_j b_{j'}$ differs, depending on whether $j=j'$ is satisfied;

$$\begin{aligned} \overline{b_j b_{j'}} &= (\bar{b})^2, & j \neq j' \\ \overline{b_j b_{j'}} &= \overline{b^2}, & j = j' \end{aligned} \quad [11]$$

where $\bar{b}$ is the average scattering length (usually known as the coherent scattering length) for all nuclei of a particular element, whilst $\overline{b^2}$ is the average of the squared scattering length for the relevant element. The double summation of eqn [10] may thus be separated into $j \neq j'$ (distinct) terms and $j=j'$ (self) terms:

$$I(\mathbf{Q}) = i(\mathbf{Q}) + \sum_l c_l \bar{b}_l^2 \quad [12]$$

where $c_l = N b_l$, N is the atomic fraction for element l and the distinct differential cross-section is

$$\begin{aligned} i(\mathbf{Q}) &= \sum_{l,l'} \overline{b_l b_{l'}} \sum_{\substack{j=1 \\ j \neq j'}}^{N_l} \sum_{j'=1}^{N_{l'}} \frac{1}{N} \\ &\times \langle \exp \{ -i\mathbf{Q} \cdot [\mathbf{R}_j(0) - \mathbf{R}_{j'}(0)] \} \rangle \end{aligned} \quad [13]$$

The l and l' summations are over the elements in the sample (e.g. for $\text{Li}_2\text{Si}_2\text{O}_5$, $l = \text{Li}, \text{Si}, \text{O}$). The j (or j') summations are then over all the N_l (or $N_{l'}$) atoms of element l (or l'), excluding terms where j and j' refer to the same atom. By the algebraic trick of adding and subtracting a $\sum_j \bar{b}_j^2 \langle j, j \rangle$ term the differential cross-section for total diffraction may be separated into its coherent and incoherent parts:

$$I(\mathbf{Q}) = \langle \bar{b}^2 \rangle_{\text{av}} S(\mathbf{Q}) + \frac{\sigma_{\text{inc}}}{4\pi} \quad [14]$$

where the structure factor is given by

$$\begin{aligned} S(\mathbf{Q}) &= \frac{1}{\langle \bar{b}^2 \rangle_{\text{av}}} \sum_{l,l'} \overline{b_l b_{l'}} \sum_{j,j'} \frac{1}{N} \langle \exp \{ -i\mathbf{Q} \cdot [\mathbf{R}_j(0) \\ &- \mathbf{R}_{j'}(0)] \} \rangle = 1 + i(\mathbf{Q}) / \langle \bar{b}^2 \rangle_{\text{av}} \end{aligned} \quad [15]$$

in which self terms ($j=j'$) are now included in the summation. The incoherent cross-section of the sample is

$$\sigma_{\text{inc}} = 4\pi \left(\langle \bar{b}^2 \rangle_{\text{av}} - \langle \bar{b} \rangle_{\text{av}}^2 \right) \quad [16]$$

in which average values for the sample are defined as

$$\begin{aligned} \langle \bar{b} \rangle_{\text{av}} &= \sum_l c_l \bar{b}_l \\ \langle \bar{b}^2 \rangle_{\text{av}} &= \sum_l c_l \bar{b}_l^2 \end{aligned} \quad [17]$$

Figure 2 The total diffraction pattern, $I(Q)$, for GeO_2 glass, shown together with the self and incoherent contributions.

$(4\pi\langle\bar{b}^2\rangle_{\text{av}}$ is the coherent cross-section for the sample). The interpretation of the coherent differential cross-section $\langle\bar{b}^2\rangle_{\text{av}}S(\mathbf{Q})$ is that this is what would be measured from a sample for which all nuclei of element l had a scattering length of $\bar{b}_l$. **Figure 2** shows the total diffraction pattern $I(Q)$ for a glass (for an isotropic sample, such as a glass, the direction of the $\mathbf{Q}$ vector is not important). It is the coherent contribution to the differential cross-section that contains interference information relating to the positions of atoms in the sample. Also shown in **Figure 2** are the self and incoherent contributions – these are featureless and contain no interference information. For most elements the incoherent cross-section is relatively small, but a notable exception to this is hydrogen for which the incoherent cross-section is very large, so that the measured experimental diffraction pattern is dominated by the incoherent contribution.

The Sources of Incoherence

The scattering length b_j for an individual nucleus (i.e. the amplitude of the neutron wave which it scatters) is not the same for all nuclei of a particular element due to two factors. These are spin incoherence and isotopic incoherence.

Spin incoherence is due to the fact that a neutron and a nucleus of spin I can form two different compound nuclei of spin $I \pm \frac{1}{2}$; the amplitude of the neutron wave scattered by the nucleus, and thus the scattering length, is generally different for the two different compound nuclei. Isotopic incoherence arises as a result

of the presence of more than one isotope of a particular element.

Total Diffraction from a Disordered Sample

The total diffraction pattern measured in reciprocal-space may be interpreted in terms of a correlation function in real-space, as is discussed below. Although this approach to neutron diffraction was developed primarily for non-crystalline systems (liquids and glasses), it is increasingly being used for powder diffraction from disordered crystalline systems as well. For a disordered crystal, the correlation function method has the advantage that it reveals the local structure, rather than the structure averaged over all unit cells that is measured by Bragg diffraction (see below).

For an isotropic sample, the diffraction pattern depends only on the magnitude Q of the momentum transfer $\mathbf{Q}$, and not its direction. In this case the distinct scattering, $i(Q)$ (eqn [12]), is related to a neutron correlation function, $T(r)$, by a Fourier transform:

$$T(r) = T^0(r) + \frac{2}{\pi} \int_0^\infty Q i(Q) \sin(rQ) dQ \quad [18]$$

$T^0(r)$ is the average density contribution to the correlation function, given by

$$T^0(r) = 4\pi r g^0 \left(\sum_l c_l \bar{b}_l \right)^2 \quad [19]$$

where g^0 is the average atomic number density in the sample, c_l is the atomic fraction for element l , and the l summation is over elements in the sample (e.g. for $\text{Li}_2\text{Mo}_2\text{O}_7$, $l = \text{Li}, \text{Mo}, \text{O}$). For example, **Figure 3** shows the neutron correlation function, $T(r)$, for GeO_2 glass, obtained by Fourier transformation of the diffraction data shown in **Figure 2**. Also shown is the average density contribution $T^0(r)$.

The total correlation function is a weighted sum of partial correlation functions:

$$T(r) = \sum_l \sum_{l'} c_l \bar{b}_l \bar{b}_{l'} t_{ll'}(r) \quad [20]$$

Each partial correlation $t_{ll'}(r)$ is related to a generalized van Hove distinct correlation function by

$$t_{ll'}(r) = 4\pi r G_{ll'}^D(r, 0) \quad [21]$$

where

$$G_{ll'}^D(\mathbf{r}, t) = \frac{1}{N_l} \sum_{j=1}^{N_l} \sum_{j'=1}^{N_{l'}} \int \langle \delta(\mathbf{r}' - \mathbf{R}_j(0)) \times \delta(\mathbf{r}' + \mathbf{r} - \mathbf{R}_{j'}(t)) \rangle d\mathbf{r}' \quad [22]$$

Figure 3 The neutron correlation function, $T(r)$, for GeO_2 glass, obtained from the data in **Figure 2**. The dashed line indicates the average density contribution, $T^0(r)$.

Although the formal definition of the partial correlation function, $t_{ll'}(r)$, may appear complicated, its interpretation is simple: $rt_{ll'}(r)dr$ is the average number of atoms of element l' which are located in a spherical shell of radius r to $r + dr$, centred on an atom of element l . For example, **Figure 4** shows how the first two peaks in the correlation function, $T(r)$, arise for an A_2X_3 material with a network structure. For the experimental data for GeO_2 glass shown in **Figure 3**, the first peak in the correlation function arises from the nearest neighbour Ge–O bonds, whilst the second peak arises from the non-bonded O–O distance in the GeO_4 tetrahedra which connect together to form the random network structure.

In the harmonic approximation the contribution to $t_{ll'}(r)$ due to a single interatomic distance r_{jk} with a root mean square thermal variation in distance of $\langle u_{jk}^2 \rangle^{1/2}$ is

$$t_{jk}(r) = \frac{n_{jk}}{r_{jk} (2\pi \langle u_{jk}^2 \rangle)^{1/2}} \exp \left(-\frac{(r - r_{jk})^2}{2 \langle u_{jk}^2 \rangle} \right) \quad [23]$$

where n_{jk} is the coordination number of k atoms around the atom j . In reciprocal-space this corresponds to

$$i_{jk}(Q) = n_{jk} \bar{b}_j \bar{b}_k \frac{\sin(Qr_{jk})}{Qr_{jk}} \exp \left(-\frac{\langle u_{jk}^2 \rangle Q^2}{2} \right) \quad [24]$$

Figure 4 A simulated neutron correlation function, $T(r)$, together with a fragment of an A_2X_3 network, showing how the peaks in the correlation function arise from the interatomic distances.

so that the total distinct scattering is given by

$$i(Q) = \sum_j \sum_k i_{jk}(Q) \quad [25]$$

Small Angle Neutron Scattering

Small-angle neutron scattering (SANS) involves the study of diffraction in the regime where the magnitude of the momentum transfer, Q , is small compared with the position of the first peak in the structure factor or the highest d -spacing Bragg peak. Thus SANS is used to study structures with dimensions of tens or hundreds of Ångströms which are large compared with interatomic distances in condensed matter. The individual scattering centres in a sample are not resolved and hence a continuous scattering length density may be introduced:

$$\rho_b(r) = \sum_i \bar{b}_i \sum_{j=1}^{N_i} \delta[r - R_j(0)] \quad [26]$$

The coherent differential cross-section observed in a SANS experiment is then

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{coh}} = \frac{1}{N} \left| \int [\rho_b(r) - \rho_b^0] \exp(iQ \cdot r) \right|^2 \quad [27]$$

where ρ_b^0 is the average scattering length density for the sample. A SANS diffraction experiment is thus sensitive to deviations of the scattering length density from the average value. To analyse data from a SANS experiment it is usually necessary to employ a model for the structures under investigation. For example, **Figure 5** shows the structure factor for a sphere with a homogenous scattering length density, surrounded by free space. As a consequence of the square modulus in eqn [27], SANS is only sensitive to the contrast in scattering length density.

Thus the same structure factor as that shown in **Figure 5** would be obtained for an empty void of the same size embedded in a homogenous medium.

Elastic Diffraction from a Crystalline Sample

Single Crystal Diffraction

An ideal crystalline material has an atomic structure which can be described in terms of infinite repetitions in three-dimensional space of a unit cell. If the sides of the unit cell are described by the three lattice vectors a , b and c , then repeating the unit cell ad infinitum by translations made up of all the possible (whole number) combinations of a , b and c will generate the ideal crystal structure.

For a single crystal the coherent elastic contribution to the differential cross-section is

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{coh el}} = \frac{(2\pi)^3}{v_0} \sum_{\tau} \delta(Q - \tau_{bkl}) |F(Q)|^2 \quad [28]$$

where v_0 is the volume of the unit cell, given by

$$v_0 = a \cdot (b \times c) \quad [29]$$

τ_{bkl} is a reciprocal lattice vector, given by

$$\tau_{bkl} = h a^* + k b^* + l c^* \quad [30]$$

where h , k and l are integers, and a^* , b^* and c^* are the unit cell vectors of the reciprocal lattice, defined by

$$a^* = \frac{2\pi}{v_0} b \times c; \quad b^* = \frac{2\pi}{v_0} c \times a; \quad c^* = \frac{2\pi}{v_0} a \times b \quad [31]$$

Figure 5 The structure factor, $S(Q)$, calculated for a homogeneous sphere of radius 20 Å and uniform density 0.05 atoms Å⁻³, surrounded by empty space.

$F(\mathbf{Q})$ is known as the structure factor:

$$F(\mathbf{Q}) = \sum_d \bar{b}_d \exp(i\mathbf{Q} \cdot \bar{\mathbf{R}}_d) \exp(-W_d) \quad [32]$$

where the d summation is taken over the atoms in the unit cell and $\bar{\mathbf{R}}_d$ is the equilibrium position of the d th atom in the unit cell. The Debye–Waller factor, W_d is a ‘damping’ term which depends upon the thermal atomic displacements. A complete treatment of the Debye–Waller factor is beyond the scope of this article, but its general behaviour is well illustrated by the simple case of a cubic Bravais lattice for which

$$2W = \frac{1}{3} Q^2 \langle u^2 \rangle \quad [33]$$

where $\langle u^2 \rangle$ is the mean square thermal displacement of an atom from its equilibrium position.

The delta function of eqn [28], $\delta(\mathbf{Q} - \boldsymbol{\tau}_{hkl})$, shows that coherent elastic scattering only occurs when the following condition is satisfied

$$\mathbf{Q} = \boldsymbol{\tau}_{hkl} \quad [34]$$

That is to say, peaks are observed in the diffraction data when the momentum transfer vector is equal to a vector of the reciprocal lattice. Such peaks are known as Bragg

peaks and eqn [34] is Bragg’s law, for diffraction from a single crystal. **Figure 6** shows a typical single crystal diffraction pattern; for every peak in the observed diffraction pattern the momentum transfer vector, $\mathbf{Q}$, satisfies Bragg’s law. Each and every Bragg peak may be identified by a unique combination of indices (h, k, l).

The diffraction pattern of a single crystal contains a wealth of information in three-dimensional reciprocal-space and, if a sufficient number of Bragg peaks is observed, a complete description of the crystal structure may be determined. The symmetry of the Bragg peaks observed in the diffraction pattern depends upon the symmetry of the crystal structure. Thus the space group of the crystal can be determined from the symmetry observed in the diffraction pattern. The positions of the Bragg peaks in reciprocal-space depend upon the lattice parameters a, b, c, α, β and γ (i.e. the magnitudes of the lattice vectors $\mathbf{a}, \mathbf{b}$ and $\mathbf{c}$, and the angles between them). Consequently the dimensions of the unit cell can be determined from the positions of the observed Bragg peaks. The intensity of each Bragg peak depends upon its structure factor, which itself depends on the positions of the atoms in the unit cell. Thus the contents of the unit cell can be determined from the integrated intensities of the observed Bragg peaks. In this way a complete description of the crystal structure may be developed from the single crystal diffraction pattern.

Figure 6 A single crystal diffraction pattern for KDCO_3 ($a = 15.2 \text{ \AA}$, $b = 5.6 \text{ \AA}$, $c = 3.7 \text{ \AA}$, $\beta = 104.8^\circ$). Reproduced courtesy of Fillaux F, Cousson A and Keen DA.

Table 2 The planar d -spacings for each crystal system

Crystal system	d -spacing
Cubic $a = b = c$ $\alpha = \beta = \gamma = 90^\circ$	$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2 + l^2}{a^2}$
Tetragonal $a = b$ $\alpha = \beta = \gamma = 90^\circ$	$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2}$
Orthorhombic $\alpha = \beta = \gamma = 90^\circ$	$\frac{1}{d_{hkl}^2} = \frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2}$
Monoclinic $\alpha = \gamma = 90^\circ$	$\frac{1}{d_{hkl}^2} = \frac{1}{\sin^2 \beta} \left(\frac{h^2}{a^2} + \frac{k^2 \sin^2 \beta}{b^2} + \frac{l^2}{c^2} - \frac{2hl \cos \beta}{ac} \right)$
Hexagonal $a = b$ $\alpha = \beta = 90^\circ$, $\gamma = 120^\circ$	$\frac{1}{d_{hkl}^2} = \frac{4}{3} \left(\frac{h^2 + hk + k^2}{a^2} \right) + \frac{l^2}{c^2}$
Rhombohedral $a = b = c$ $\alpha = \beta = \gamma$	$\frac{1}{d_{hkl}^2} = \frac{(h^2 + k^2 + l^2) \sin^2 \alpha + 2(hk + kl + lh)(\cos^2 \alpha - \cos \alpha)}{a^2(1 + 2\cos^3 \alpha - 3\cos^2 \alpha)}$
Triclinic $a \neq b \neq c$ $\alpha \neq \beta \neq \gamma$	$\frac{1}{d_{hkl}^2} = \frac{\frac{h^2 \sin^2 \alpha}{a^2} + \frac{k^2 \sin^2 \beta}{b^2} + \frac{l^2 \sin^2 \gamma}{c^2} + \frac{2hk}{ab}(\cos \alpha \cos \beta - \cos \gamma) + \frac{2kl}{bc}(\cos \beta \cos \gamma - \cos \alpha) + \frac{2lh}{ac}(\cos \gamma \cos \alpha - \cos \beta)}{1 + 2\cos \alpha \cos \beta \cos \gamma - \cos^2 \alpha - \cos^2 \beta - \cos^2 \gamma}$

It should be noted that the structure factor, $F(\mathbf{Q})$, used in crystallography (eqn [32]) has a different meaning and definition to the structure factor, $S(\mathbf{Q})$, used in studying diffraction from disordered samples (eqn [15]). In addition, there is a fundamental difference between the Bragg scattering observed for crystals and the total diffraction cross-section in that the Bragg scattering is purely elastic, whereas total diffraction involves both elastically and inelastically scattered neutrons. This has the consequence that the correlation function which is addressed by the study of Bragg diffraction is the time-averaged correlation function $G_{II'}^D(\mathbf{r}, \infty)$ (see eqn [22]). Hence, for a crystal, the Bragg scattering provides information which is in principle complementary to total diffraction, which yields the instantaneous correlation function $G_{II'}^D(\mathbf{r}, 0)$.

Powder Diffraction

Although single crystal diffraction is the most powerful method for studying the structure of crystals, the powder diffraction method is also frequently used to reveal structural information for crystalline materials. In this case the sample is not a single crystal, but is instead a powder which contains numerous microcrystals, such that all orientations are equally likely. The observed

**Figure 7** Bragg planes with spacing d_{hkl} which give rise to the hkl Bragg peak.

diffraction pattern is then an average of eqn [28] over all possible relative orientations between the momentum transfer vector $\mathbf{Q}$ and the crystal lattice. The measured diffraction pattern does not depend on the orientation between the sample and the neutron beam, and it is usual to identify each Bragg peak in the diffraction pattern by

Figure 8 The neutron diffraction pattern for polycrystalline silicon together with a fit obtained by profile refinement. Also shown is the residual divided by experimental error for the fit and vertical bars which indicate the positions of the allowed reflections under the space group $Fd3m$.

its d -spacing, d_{hkl} defined by

$$|\tau_{hkl}| = \frac{2\pi}{d_{hkl}} \quad [35]$$

Combining this definition with eqns [8] and [34] leads to Bragg's law for powder diffraction:

$$2d_{hkl} \sin \theta = \lambda \quad [36]$$

Bragg's law indicates the combinations of θ and λ for which Bragg peaks are observed in the powder diffraction pattern of a crystalline material. **Table 2** gives the formulae for the possible d -spacings of each of the crystal systems. Note that some of the d -spacings predicted by these formulae may not occur as peaks in the diffraction pattern, depending on the symmetry of the crystal structure; some Bragg peaks may have structure factors equal to zero, owing to the crystal symmetry, with the result that they are not allowed. The d -spacing of a Bragg peak may be interpreted as being the spacing for a set of planes of atoms in the crystal such that reflection from these planes gives rise to the Bragg peak (see **Figure 7**).

Figure 8 shows the relatively simple powder diffraction pattern of polycrystalline silicon, measured by time-of-flight neutron diffraction. Each allowed Bragg peak for the crystal structure is observed as a sharp peak in the diffraction pattern. A fundamental difference between single crystal and powder diffraction is that the single crystal diffraction pattern has the full directional information described by eqn [28], whereas for the powder diffraction pattern this information has been collapsed down into a one-dimensional function. This

difference has two important consequences: firstly, the loss of directional information makes it very much more difficult to deduce the symmetry of the crystal lattice from powder diffraction data. For this reason, powder diffraction is more commonly used to study the contents of the unit cell for crystals whose symmetry is already known; secondly, the Bragg peaks are much more likely to suffer from significant overlap in a powder diffraction pattern than in single crystal data. This means that it may not be possible to determine the structure factors of the reflections by integrating the intensities of individual peaks and instead the profile refinement method must be used to analyse the data. The profile refinement method involves fitting the whole of the diffraction pattern simultaneously in order to extract structural information. This method requires an explicit knowledge of the resolution function of the neutron diffractometer.

Introduction

Nitrogen has two stable isotopes, ^{14}N and ^{15}N , both of which are NMR active. In addition nitrogen is one of the most important atoms in organic, inorganic and biochemistry due to its occurrence in a variety of valence states with various types of bonding and stereochemistry. Thus the nuclear shieldings, spin–spin couplings and relaxation data obtained from nitrogen NMR studies are of widespread interest to molecular scientists. The relatively large range, in excess of 1000 ppm, found for the nitrogen chemical shifts of organic compounds indicates that the shifts are sensitive to relatively small electronic changes in the environment of the nitrogen atom. Consequently a change of solvent or substituent can have a very significant effect on nitrogen chemical shifts.

Solvent effects can be produced by specific interactions, such as protonation or hydrogen bonding and nonspecific interactions which may arise from solvent polarity effects. Both of these types of interaction are found in studies of solvent effects on nitrogen nuclear shieldings. The extent of substituent effects depends upon the position of substitution and the electronic nature of the substituent.

Most spin–spin couplings involving nitrogen nuclei are relatively small, and both positive and negative couplings are found. Both the sign and the magnitude of the couplings are influenced by the orientation of the nitrogen lone pair electrons with respect to the direction of the bond through which the coupling occurs.

^{14}N nuclear relaxation is usually dominated by the quadrupolar mechanism which results in broad lines both in the nitrogen NMR spectrum and in the spectra of nuclei spin–spin coupled to nitrogen. The relaxation of ^{15}N is controlled by one, or more, of the less efficient processes.

Nuclear Properties

In natural abundance nitrogen exists in two isotopic forms, the most common is ^{14}N which is 99.635% abundant and has a spin of 1, the other is ^{15}N which has an abundance of 0.365% and a spin of $\frac{1}{2}$. Thus both isotopes are NMR active. The first report of a ^{14}N NMR spectrum appeared in 1950 when NMR was still very much in its infancy. However, both nitrogen isotopes have low NMR sensitivities relative to that of a proton in the

same applied magnetic field; these are 0.00101 and 0.00104 for ^{14}N and ^{15}N respectively. Coupled with the relatively high cost of ^{15}N isotopic enrichment, the low sensitivities ensured that nitrogen NMR studies were not too widespread until the mid-1960s. Since then improvements in both NMR instrumentation and experimental techniques have generated a wide and growing interest in nitrogen NMR spectroscopy. Today the NMR spectra of both isotopes are normally studied at natural abundance due to the increased sensitivity which is currently available in high-field NMR spectrometers.

The fact that the ^{14}N nucleus has a spin of 1 implies that it has an electric quadrupole moment, which is able to interact with local electric field gradients in the molecule and produces rapid nuclear relaxation. A consequence of this is that ^{14}N NMR signals can be very broad, as much as a few kilohertz, and overlapping. Since the quadrupolar relaxation mechanism is independent of the magnitude of the magnetic field used in the NMR experiment, with a high-field spectrometer the ^{14}N signals appear to be relatively sharper and less overlapping than they do in a lower field instrument. Hence the widespread availability of high-field spectrometers has led to a renaissance of interest in ^{14}N NMR studies both from the point of view of increased sensitivity and from the diminishing in importance of the effects of quadrupolar relaxation in high-resolution NMR spectroscopy.

Chemical Shifts

The most widely used nitrogen chemical shift standard is neat nitromethane. This is used as an external reference by typically employing a set of coaxial tubes with the reference material in the inner one. Ideally an internal chemical shift standard is desirable since this removes the necessity of correcting for any magnetic bulk susceptibility difference between the sample and the standard. However, in nitrogen NMR this is usually not an option since the nitrogen shielding of a chemical shift standard may vary by up to 40 ppm due to molecular interactions in liquids and solutions. A possible candidate for the role of internal nitrogen chemical shift standard is molecular nitrogen, N_2 . This is present in nearly all solutions and gives a clear sharp signal in ^{14}N NMR spectra. However, its shielding is not entirely immune from solvent effects;

Figure 1 Characteristic nitrogen shielding ranges for various classes of molecules and ions (referred to external neat nitromethane).

Figure 1 Continued

Figure 1 Continued

Figure 1 Continued

Figure 1 Continued

a range of about 2 ppm is found for solvent-induced variations. As shown in **Figure 1** the overall range of nitrogen chemical shifts for organic compounds is in excess of 1000 ppm.

Only approximate ranges are given as a general guide, and in practice most of them may be further divided into subsections to reflect the finer points of variation in molecular structure. The extent of the chemical shift range shown in **Figure 1** shows clearly that spectral assignments are usually very straightforward in nitrogen NMR. In general those nitrogen environments with σ -bonding only, and no nitrogen lone-pair electrons, are the most highly shielded ones, e.g. alkylamines. In contrast, when the nitrogen atom is involved in π -bonding and lone-pair electrons are available, then the shielding is decreased by a contribution from the paramagnetic term in the shielding expression, e.g. nitrites and nitroso compounds. In a molecular system where nitrogen is involved in multiple bonding an increase in shielding or decrease in chemical shift is observed if the nitrogen lone-pair is replaced by a covalent bond, e.g. in passing from pyridine to the pyridinium ion.

Solvent Effects on Nitrogen Shielding

Solvent effects on nitrogen shieldings can be remarkable and need to be carefully considered in the interpretation of nitrogen chemical shifts in terms of molecular structure. So far the largest variation reported in nitrogen chemical shift for a neutral molecular species, as a function of solvent, is about 50 ppm for pyridazine (1,2-diazine). This is shown in **Table 1** together with some other examples of typical solvent effects on nitrogen shieldings.

These data are quoted from systematic studies on dilute solutions where bulk susceptibility effects have been taken into account and the solvents used were chosen to encompass a broad range of properties.

In ionic species the largest solvent-induced variation of nitrogen shielding has been observed for the nitroso moiety of $[\text{C}(\text{NO})(\text{CN})_2]^- \text{K}^+$ in water and a number of alcohols. The range is about 200 ppm and is related to the $\text{p}K_{\text{a}}$ values of the solvents. The data reported in **Table 1** have been analysed in terms of the Kamlet–Taft system of solvent properties. This can be represented by the following expression:

$$\sigma(i, j) = \sigma_0 + a_i \alpha_j + b_i \beta_j + s_i (\pi_j^* + d_i \delta_j)$$

where i denotes a particular nitrogen atom in the molecule examined, j denotes the solvent, σ is the relevant nitrogen shielding, σ_0 is the shielding observed in a solution using cyclohexane as a standard inert solvent, α_j is the hydrogen-bond donor strength of the solvent j , β_j is the corresponding hydrogen-bond acceptor strength of

Table 1 Examples of the range of solvent effects on nitrogen shieldings

Molecule	Range of solvent effects on nitrogen shielding (ppm)
Pyridine	38
Pyridazine (1,2-diazine)	49
Pyrimidine (1,3-diazine)	18
Pyrazine (1,4-diazine)	16
1,3,5-Triazine	11
Pyridine <i>N</i> -oxide	30
Indolizine and azaindolizine systems	
Bridgehead nitrogen	1–3
Pyridine-type nitrogen	26–32
Alkyl cyanides (nitriles)	22–26
Nitromethane	11
Methyl nitrate	5
<i>t</i> -Butyl nitrite	26
Methyl isothiocyanate	10
Azo bridge	2
Dinitrogen	1.3

the solvent, π_j^* represents the solvent polarity/polarizability and δ_j is a correction for the ‘superpolarizability’ of aromatic and highly chlorinated solvents. The terms a , b , s and d are the relevant nitrogen shielding responses to the individual bulk solvent properties. If a solute nitrogen atom is protonated by the solvent then a large increase in shielding, often in excess of 100 ppm, occurs. Hydrogen-bonding from solvent to a solute nitrogen atom usually also produces a smaller increase in nitrogen shielding. In terms of ppm per scale unit of α the increase is about 21 for the nitrogen atoms of pyridine and pyridazine, about 17 for pyridine-type nitrogen atoms in the five-membered ring moieties of azaindolizines and about 10 for covalent cyanides. The magnitudes of these solvent-induced shifts reflect the relative strengths of the hydrogen-bonds concerned.

Since the d term in the above equation is usually negligibly small in practice, nitrogen shielding responses to changes in solvent polarity are normally represented by the s term. In terms of ppm per unit scale of π^* the values found for s may be of either sign. A positive sign indicates an increase in nitrogen shielding as the polarity of the medium increases. For pyridazine the value is about 13, whereas for other pyridine-type nitrogen atoms in azines and azaindolizines it is in the region of 5. The value of s is also found to be positive for the nitrogen atoms of covalent cyanides, whereas it is negative for covalent nitrites, isothiocyanates, C-nitro and O-nitro groups. The sign of s is related to the orientation of bond dipoles in the vicinity of the nitrogen atoms concerned. This point of view is supported by molecular orbital calculations incorporating the Solvaton model.

In general the *trans*-azo bridge nitrogen atoms reveal only a very small shielding variation as the solvent is

changed. An exception occurs when tri-fluoroethanol is used as solvent. This is probably due to a hydrogen-bonding interaction with the π -electrons of the N=N bond. The nitrogen shieldings of nitroso groups show a diversity of solvent-induced effects. The observed range for $\text{Bu}^t\text{-NO}$ is about 10 ppm. The major contribution to this range of solvent-induced shielding changes arises from variations in solvent polarity. This is probably due to the fact that the bulky *tert*-butyl group prevents any significant amount of solvent-to-solute hydrogen bonding in this case. In contrast, the O-nitroso groups in covalent nitrites show much larger solvent-induced nitrogen shielding ranges which include significant contributions from solvent-to-solute hydrogen bonding effects.

Substituent Effects on Nitrogen Shielding

A general trend in the values of the nitrogen shielding, which is observed for a large variety of structures, is for the shielding to decrease along the sequence, N-CH_3 , $\text{N-CH}_2\text{R}$, N-CHR_2 , N-CR_3 , where R is an alkyl group. This is referred to as the β effect and is useful for locating nitrogen-containing functional groups within a hydrocarbon chain. Other comparable effects may arise when alkyl groups replace hydrogen atoms at other positions in an aliphatic chain, as shown in Figure 2.

For aliphatic amines the nitrogen shielding decreases by 7.8 ppm when an alkyl group is introduced into the α position. It decreases by 18.6 ppm when the introduction occurs at the β position. If the alkyl group appears at the γ position, the opposite effect is observed and the shielding increases by 2.4 ppm, whereas the introduction of the alkyl group at the δ position produces a further decrease of nitrogen shielding by 2.5 ppm. Local molecular interactions can also be monitored by means of changes in nitrogen chemical shifts. Interactions of protein fragments provide an example of this, as shown in Figure 3.

Escherichia coli thioredoxin has characteristic sites which are affected by the transformation between its reduced and oxidized forms. Variations in the nitrogen chemical shifts of the amino acid fragments have been used in a study of the binding of Mg^{2+} , Ca^{2+} and Ba^{2+} to *E. coli* ribonuclease HI.

Figure 2 Effect on nitrogen chemical shifts caused by replacing hydrogen atoms by alkyl groups in an aliphatic chain.

Spin-Spin Couplings

Owing to the normally rapid quadrupolar relaxation of ^{14}N nuclei, spin-spin coupling interactions between ^{14}N and other nuclei are only seldom observed. Thus most couplings involving nitrogen nuclei are usually measured from the NMR spectra of ^{15}N -coupled nuclei. Spin-spin couplings between a nucleus X and ^{14}N and between X and ^{15}N are interconvertible by means of the following equation:

$$J(^{15}\text{N-X}) = -1.4027 J(^{14}\text{N-X})$$

Spin-spin couplings involving ^{15}N play an important role in the application of nitrogen NMR to the structure determination of nitrogen-containing molecules, since their values are often characteristic of the type and number of intervening bonds between the coupled nuclei.

Values of $^1J(^{15}\text{N-}^1\text{H})$ are negative in sign and considerably larger in magnitude than spin-spin couplings between this pair of nuclei when separated by more than one bond. If proton exchange occurs within a given molecule then the observed value of the $^{15}\text{N-}^1\text{H}$ coupling represents a weighted average which includes coupling with the proton at all its sites of residence. Such a situation arises with some porphyrins, for example octaethylporphyrin in CDCl_3 . At -53°C the ^{15}N NMR spectrum consists of a singlet and a doublet split by 98 Hz; this latter value is typical of $^1J(^{15}\text{N-}^1\text{H})$ in pyrrole-type systems. At $+28^\circ\text{C}$ only a quintet is observed split by 24 Hz. This indicates that the NH protons are exchanging amongst the four nitrogen atoms at higher temperatures and that the long-range N-H couplings are close to zero.

If major structural differences between molecules are considered then values of $^1J(^{15}\text{N-}^1\text{H})$ often show a reasonable correlation with the s-characters of the N-H bonds involved. However, notable exceptions are known and thus it may be unsound to try to estimate the s-character of a given N-H bond from the observed value of the $^1J(^{15}\text{N-}^1\text{H})$ interaction. Any such correlation would have to rely on the dominance of the contact term

Figure 3 Effect on nitrogen shielding due to interactions of protein fragments.

to the spin–spin coupling interaction. In cases where this dominance occurs then a simple distinction may be made between a variety of structures by means of $^1J(^{15}\text{N}-^1\text{H})$ values.

Since absolute values of $^1J(^{15}\text{N}-^1\text{H})$ are normally of the order of 100 Hz, the collapse of multiplet patterns in the ^{15}N NMR spectra of NH moieties can be used to monitor proton exchange processes which occur at rates of around 100 s^{-1} . Some examples where this technique has been used are ureas, lactams, arginine and histidine. Values of $^2J(^{15}\text{N}-^1\text{H})$ across a saturated carbon atom are normally small in magnitude and positive in sign. Such couplings reveal a dependence of the orientation of the lone-pair electrons on the nitrogen atom with respect to the C–H bond. The largest values are observed when the bond is *cis* to the lone pair. If the intervening carbon atom is tricoordinate, then the value of $^2J(^{15}\text{N}-^1\text{H})$ is much larger, about 15 Hz. When the coupling occurs in an imino-type moiety the value of $^2J(^{15}\text{N}-^1\text{H})$ depends critically upon the bond structure at the nitrogen atom in question. If the nitrogen atom has a lone pair of electrons, the coupling is usually large in magnitude and negative in sign. If protonation of the lone pair electrons occurs, then the absolute value of the coupling decreases significantly. An even more dramatic change occurs when an N-oxide is formed; the resulting coupling may then have a small positive value. Similar observations have been made for cyclic lactams of the uracil type; if the nitrogen has a lone pair of electrons, the observed value of $^2J(^{15}\text{N}-^1\text{H})$ is large, e.g. the anion of 3-methyluracil. The coupling is considerably reduced when a hydrogen atom is attached to the nitrogen.

Values of $^3J(^{15}\text{N}-^1\text{H})$ in saturated systems are often larger than the corresponding two-bond couplings. However, the three-bond couplings depend upon the dihedral angle between the N–C and C–H bonds and attain maximum values for the *cis* and *trans* arrangements and a minimum value when the dihedral angle is around 90° . Thus for the *gauche* configuration, where the dihedral angle takes a value of about 60° , rather small absolute values of $^3J(^{15}\text{N}-^1\text{H})$ are expected. For unsaturated systems, e.g. aza-aromatic structures, the values of $^3J(^{15}\text{N}-^1\text{H})$ do not differ appreciably in absolute magnitude from those found in saturated systems. This is in contrast to the situation found for values of $^2J(^{15}\text{N}-^1\text{H})$.

In general, few values have been found for $^{15}\text{N}-^1\text{H}$ couplings across more than three bonds. Those reported for pyridine, its cation and its N-oxide are small and positive in sign, whereas those for nitrobenzene are small and negative in sign.

Usually the values of $^1J(^{15}\text{N}-^{13}\text{C})$ are negative in sign and less than ~ 35 Hz. However, the range of values reported is from $+4.9$ Hz for an oxaziridine derivative to -77.5 Hz for 2,4,6-trimethylbenzonitrile N-oxide. Some attempts have been made to relate $^1J(^{15}\text{N}-^{13}\text{C})$ data to

the amount of s-character of the N–C bonds. Such a correlation would depend upon the dominance of the contact interaction to the spin–spin coupling and this is not always the case in practice. In general, nitrogen–carbon couplings across one bond are larger than those across more bonds. However, there are exceptions. These usually arise when the nitrogen atom in question has a lone pair of electrons in an orbital with high s-character. Examples are provided by pyridine-type nitrogen atoms in azines and azoles and imino-type nitrogen atoms in imines and oximes. For pyridine the value of $^1J(^{15}\text{N}-^{13}\text{C})$ is $+0.62$ Hz, that for $^2J(^{15}\text{N}-^{13}\text{C})$ is $+2.53$ Hz and for $^3J(^{15}\text{N}-^{13}\text{C})$ it is -3.85 Hz. In general it pays to be cautious in N–C spin–spin coupling data to determine the presence, or absence, of specific N–C bonding arrangements.

Values of $^2J(^{15}\text{N}-^{13}\text{C})$ are usually smaller than those across one bond in saturated systems. If the coupling is across a carbonyl carbon atom then the absolute value of $^2J(^{15}\text{N}-^{13}\text{C})$ increases significantly to about 4–12 Hz. Thus a means is provided for distinguishing between saturated and unsaturated molecular fragments. If the nitrogen atom involved in the coupling has a lone pair of electrons in an orbital with significant s-character then the sign and magnitude of $^2J(^{15}\text{N}-^{13}\text{C})$ depend critically upon whether the coupled carbon nucleus is *cis* or *trans* to the lone-pair electrons.

Three-bond $^{15}\text{N}-^{13}\text{C}$ couplings are usually negative in sign and less than 5 Hz. For saturated systems attempts have been made to relate values of $^3J(^{15}\text{N}-^{13}\text{C})$ to the dihedral angle between the C–C and N–C bonds. Usually the rather small values observed for the couplings give rise to considerable errors in any such angle determination.

Couplings between ^{15}N and ^{13}C across more than three bonds are usually less than 1 Hz in absolute magnitude. A lone exception is a derivative of 1,2,4-triazine where a value of 3.9 Hz has been reported for the four-bond coupling between 1-N and a methyl group attached to a vinyl substituent.

The largest $^1J(^{15}\text{N}-^{15}\text{N})$ values are found for N-nitrosoamines and the smallest for hydrazino moieties, nitramines and molecular N_2 . Generally, values occur within the range of 10–20 Hz for N=N moieties. Exceptions are found when the moieties are charged, as they are in diazo compounds and azides, where the coupling is less than 10 Hz. The values of $^2J(^{15}\text{N}-^{15}\text{N})$ across a nitrogen atom are close to zero in azides but may be as large as 11 Hz in some isomers of imino-type triazenes. Two-bond $^{15}\text{N}-^{15}\text{N}$ couplings across a carbon atom can also be significant, particularly when the carbon atom in question is tricoordinate.

Values of $^1J(^{31}\text{P}-^{15}\text{N})$ cover a broad range and may be either positive or negative in sign. Hence, if only the absolute value is known, their interpretation is not always

straightforward. It seems that the value observed depends critically upon the dihedral angle between the nitrogen and phosphorus lone pairs of electrons. A significant algebraic decrease in the value of $^1J(^{31}\text{P}-^{15}\text{N})$ occurs upon passing from tricoordinate to tetracoordinate phosphorus atoms.

A number of values of $^2J(^{31}\text{P}-^{15}\text{N})$ have been reported for couplings across metal atoms in various complexes. For square-planar complexes a clear distinction is found in the values of the couplings depending upon whether the ligands in question are *cis* or *trans* to each other.

Values of $^1J(^{19}\text{F}-^{15}\text{N})$ are positive in sign and usually between 150 and 460 Hz. Nitrogen-fluorine couplings across two or more bonds are also significant in magnitude.

$^1J(^{195}\text{Pt}-^{15}\text{N})$ couplings have large absolute values, usually ranging from 100 to 580 Hz. They are found to be sensitive to the nature of the ligands, as well as to their arrangement in square-planar complexes. Normally the largest influence on the value of the coupling is exerted by the ligand that is *trans* to the nitrogen atom involved.

Nitrogen Nuclear Relaxation

Since the ^{14}N nucleus has an electric quadrupole moment, this may interact with local electric field gradients in the molecule, to produce rapid nuclear relaxation and broad NMR transitions. The electric field gradient may vary due to molecular motion and this variation may be studied by means of ^{14}N NMR. A combination of the ^{14}N quadrupolar relaxation rate and ^{13}C - ^1H dipolar relaxation data can be used to determine the rotational correlation times for motion about each principal molecular axis. This approach has been applied to pyrimidine, pyridazine and pyrazine. ^{14}N relaxation data for formamide are found to be very sensitive to the presence of both cations and anions. These results provide direct evidence for specific ion-amide interactions and a tentative model for the interaction of electrolytes in liquid formamide.

^{14}N NMR line widths may be used as an aid to the assignment of nitrogen chemical shifts. In particular, a nitrogen atom bearing a partial positive charge tends to

have a relatively small local electric field gradient associated with it, consequently its ^{14}N signal will be rather sharp. This approach has been extensively used in studies on meso-ionic compounds.

^{15}N nuclear relaxation usually occurs through varying contributions from the dipole-dipole, spin-rotation, chemical shielding anisotropy and scalar coupling mechanisms. If the ^{15}N nucleus is directly bonded to a proton then the dipole-dipole interaction is normally dominant. In the case of *trans*-azobenzene, the ^{15}N relaxation occurs by a combination of the spin-rotation, dipole-dipole and chemical shielding anisotropy interactions. The relative proportions of these mechanisms contributing to the relaxation are found to vary considerably over the temperature range from 5 °C to 80 °C. The ^{15}N relaxation times of a number of aldoximes and ketoximes are between 25 s and 50 s. In general the dipole-dipole interaction is the major contributor, but other mechanisms can account for more than half of the measured ^{15}N relaxation in these molecules.

Symbols

F, ν	frequency
i	$\sqrt{-1}$
m	number of complex coefficients
M, N	number of complex points
p	probability distribution
s_k	k th point in free induction decay
S_n	n th point in spectrum
$S(p)$	Shannon informational entropy
$S_p(\nu)$	phased spectrum
$s(t)$	free induction decay
t_1	evolution time
t_2	real time
t_e	exponential time constant
t_g	Gaussian time constant
t_s	time shift of Gaussian
T	decay constants
W	line width
$W(t)$	weighting function
α_j	j th complex amplitude
β_j	j th complex exponential
δ	delay time
ϕ	phase shift

Computers play a central part in modern NMR spectroscopy. Their use for the real-time control of pulsed NMR experiments has enabled the development of multiple pulse techniques such as two-dimensional NMR; this article deals with the part played by computers in the acquisition, processing and presentation of experimental NMR data.

All NMR experiments rely on the excitation of a nuclear spin response by a radiofrequency magnetic field, usually in the form of a short pulse or pulse sequence. This generates a rotating nuclear magnetic moment, which induces a small oscillating voltage in the probe coil: a ‘free induction decay’ (FID). The spectrometer receiver amplifies this voltage, shifts it down into the audio frequency range, and filters out high-frequency components before it is digitized by an analogue-to-digital converter (ADC). In modern instruments two receiver channels with phases 90° apart are used (‘quadrature detection’), allowing the relative signs of frequencies to be distinguished. From this point onwards the signal is handled digitally until it is presented to the

experimenter as a printed spectrum or an interactive spectral display. The three main stages of processing are first, the acquisition of a filtered, averaged time-domain recording of the nuclear spin response; second, the generation of a frequency-domain spectrum, usually but not always by Fourier transformation; and third, postprocessing of the spectrum to aid its interpretation. The three stages are summarized briefly below, followed by more detailed discussions of the techniques used and some practical illustrations.

Data Acquisition

NMR experiments generally require the coaddition of a number of recordings of the nuclear spin response (‘transients’), often using different permutations of radiofrequency pulse and receiver phases (‘phase cycling’). The data are recorded as a set of complex numbers which sample the in-phase and quadrature NMR signals as a function of time. Early Fourier transform spectrometers had limited word length and required some scaling of the data before coaddition, but this is no longer necessary and successive transients are simply added to memory. Many recent spectrometers interpose a stage of digital signal processing before data summation: a wide receiver band width is used, and data are digitized very rapidly. These oversampled data are then filtered digitally before downsampling and addition to memory, giving better filtration of unwanted noise and signals, better effective ADC resolution, and less baseline distortion.

In two-dimensional (2D) NMR a series of FIDs is acquired using a pulse sequence containing a variable evolution period, which is incremented regularly to map out the behaviour of the nuclear signal as a function both of real time t_2 during the FID, and of the evolution time t_1 . A typical 2D NMR experiment might acquire 512 FIDs of 1024 complex points, which would then be doubly Fourier transformed as a function of the two time variables. 3D and 4D NMR extend the principle to two and three evolution periods respectively.

Spectrum Generation

To make the raw experimental data interpretable they must be converted into a frequency-domain spectrum.

The classical, and commonest, method is discrete Fourier transformation. This is a linear operation: the information content of the data is unchanged. Alternative methods such as maximum entropy reconstruction and linear prediction are nonlinear, changing the information content. In Fourier processing a weighting function is usually applied to the time-domain data before transformation; a DC correction based on the last portion of the data may also be performed. After weighting and any zero-filling (see below), the fast Fourier transform (FFT) algorithm is used to produce the frequency spectrum. The resultant spectrum consists of a set of complex numbers sampling a defined frequency range at equal intervals. In general the real and imaginary parts of the spectrum will both be mixtures of absorption mode and dispersion mode signals; a spectrum suitable for display and analysis is obtained by taking linear combinations of the real and imaginary data ('phasing'), or, if that is not possible, by taking the modulus ('absolute value mode') or square modulus ('power mode').

In 2D NMR, weighting and zero-filling are carried out on the FIDs as normal, but after Fourier transformation with respect to t_2 to give a series of spectra $S(t_1, F_2)$ the data matrix is transposed to give a set of 'interferograms' $S(F_2, t_1)$. A second Fourier transformation, with respect to t_1 , yields the 2D spectrum $S(F_1, F_2)$. Because most coherence transfer processes cause amplitude rather than phase modulation as a function of t_1 , information on the signs of F_1 frequencies is usually missing; it can be recovered by making two measurements using different phase cycles. If the two sets of measurements are combined before Fourier transformation, converting amplitude modulation into phase modulation, absolute value mode presentation is generally required because individual signals will show a 'phase-twist' line shape; this is also the case with simple experiments which use pulsed field gradients for coherence transfer pathway selection. If the two data sets are recombined appropriately after the first Fourier transformation, both phase cycled and pulsed field gradient 2D experiments can be made to yield pure double absorption mode line shapes. Two common recombination schemes are the 'hypercomplex' method of States, Haberkorn and Ruben, and the time-proportional phase incrementation (TPPI) method of Marion and Wüthrich.

Postprocessing

Many chemical questions can be answered with a simple spectrum, but to extract all the useful information from an NMR experiment it can require a wide range of data processing methods. Integration (usually after baseline correction) and peak picking allow the relative numbers of spins responsible for different multiplets to be found, and chemical shifts and scalar couplings to be measured. Better measures of signal intensity and line shape can be

found by least-squares fitting, if necessary in conjunction with line shape correction by reference deconvolution. Computers can also aid in the analysis of strongly coupled spectra and the spectra of dynamic systems.

Zero-Filling

Data acquisition produces a set of N complex points, sampled at equal time intervals Δt , which describe the nuclear FID as $2N$ independent pieces of information. Discrete Fourier transformation of these data will produce a spectrum of N complex points, at frequency intervals $1/(N\Delta t)$. A final absorption mode spectrum will contain just N independent pieces of information, only half the amount originally acquired; the remaining N points form the dispersion mode spectrum. Full use of the experimental data can be achieved if N complex zeroes are appended to it before Fourier transformation ('zero-filling'). Transforming N data points plus N zeroes generates a spectrum of $2N$ complex points, at frequency intervals $1/(2N\Delta t)$ Hz. The $2N$ real points are independent, and contain the same information as the $2N$ imaginary points: the real and imaginary data are correlated, so the total information content of the spectrum is unchanged. Zero-filling thus improves the digital resolution of the frequency spectrum twofold, as can be seen from **Figure 1**. Appending more than N zeroes before transformation cannot increase the information content of the spectrum: the extra data points obtained simply interpolate between those produced by a single zero-filling.

Time-Domain Weighting

All experimental NMR signals decay, sooner or later: most well-designed experiments sample the signal until it has decayed close to zero. The later stages of the recorded data contain less signal, but the noise remains more or less constant. Recording for too short a time will lose valuable data; recording for too long will emphasize the noise relative to the signal. The widths of spectral lines depend on the rate of decay of the NMR signal: resolution can be improved if the natural decay of the signal is counteracted. Both issues can be addressed by weighting the time-domain signal before Fourier transformation. The choice of weighting function determines the compromise between resolution and signal-to-noise ratio in the resultant spectrum.

The signal-to-noise ratio of a spectrum can be optimized by multiplying the experimental signal by a weighting function which matches the experimental decay envelope: 'matched filtration'. The Fourier transform of an exponential decay with time constant T is a Lorentzian line shape with a full width at half height of $1/(\pi T)$ Hz. Thus to obtain the best signal-to-noise ratio for a Lorentzian line of width W Hz the experimental

Figure 1 Spectra of a doublet with splitting 2 Hz, centred at -10 Hz, calculated for a 64 complex point FID with (a) no zero-filling; (b) one zero-filling, to 128 complex points; and (c) four zero-fillings, to 1024 complex points. The splitting becomes visible after one zero-filling; further zero-filling is equivalent to interpolation between the data points with a $\sin(x)/x$ function.

data should be multiplied by a decaying exponential of time constant $1/(\pi W)$ s. This gives a spectrum with optimum signal-to-noise ratio, at the expense of a doubling of the line width to $2W$ Hz. Where a spectrum with poor signal-to-noise ratio contains lines with a range of widths it can be helpful to try exponential weighting with several different time constants.

Time-domain weighting is equivalent to frequency-domain convolution. The convolution theorem states that the Fourier transform of the product of two functions $a(t)$ and $b(t)$ is the convolution of the two individual transforms $A(v)$ and $B(v)$:

$$\begin{aligned}
 \text{FT}^{-}[a(t) \times b(t)] &= \int_{-\infty}^{\infty} a(t) \times b(t) \exp(-2\pi i v t) dt \\
 &= \int_{-\infty}^{\infty} A(v') \times B(v - v') dv' \\
 &= \text{FT}^{-}[a(t)] \otimes \text{FT}^{-}[b(t)] \\
 &= A(v) \otimes B(v)
 \end{aligned}
 \quad [1]$$

Figure 2 75.4 MHz spectra of the ^{13}C triplet of deuteriobenzene in the ASTM (American Society for Testing and Materials) sensitivity test sample (60% deuteriobenzene/40% dioxane), with and without matched filtration. The unweighted spectrum (a) shows a signal-to-noise ratio of 18:1; the same data given an exponential multiplication with a time constant $1/(3\pi)$ s before Fourier transformation, corresponding to a 3 Hz Lorentzian line broadening, show (b) a signal-to-noise ratio of 92:1. An acquisition time of 5.462 s was used, with a spectral width of 12 000 Hz and one zero-filling. The insets show expansions of the triplet signal, illustrating the broadening of the lines and the smoothing of the noise caused by the exponential multiplication.

where $\text{FT}^{-}[\]$ indicates Fourier transformation and $\otimes$ denotes convolution. Thus time-domain exponential weighting is equivalent to convolution, or smoothing, with a Lorentzian lineshape in the frequency domain. Matched filtration corresponds to smoothing the raw experimental spectrum with a function which matches the experimental line shape, as **Figure 2** illustrates.

Time-domain weighting is also extensively used for resolution enhancement. Since this emphasizes the later part of the experimental signal, the noise energy is increased with respect to the signal energy, and resolution enhancement reduces the signal-to-noise ratio of the resultant spectrum. The aim of resolution enhancement is to reduce line widths without degrading the signal-to-noise ratio unacceptably. The natural decay of individual NMR signals is normally exponential, but countering this decay by multiplication with a rising exponential would lead to steeply rising noise. To stop the exponential rise in noise a further weighting using a function with a steeper decline is required. A weighting function $W(t)$ composed of a rising exponential with time constant t_e and a falling Gaussian with time constant t_g

$$W(t) = \exp(+t/t_e) \exp[-(t/t_g)^2] \quad [2]$$

is generally the method of choice for resolution enhancement. $W(t)$ can also be written as a time-shifted Gaussian

$$W(t) = \exp(+t_s^2/t_g^2) \exp[-(t - t_s)^2/t_g^2] \quad [3]$$

where $t_s = t_g^2/(2t_e)$. If t_e is equal to the decay constant of the experimental NMR signal, then multiplication by $W(t)$ before Fourier transformation converts a Lorentzian lineshape of width $1/(\pi t_e)$ Hz to a Gaussian of width $(2/\pi t_g)\sqrt{\log_e 2}$ Hz. Since spectra normally contain a range of line widths, it is usually necessary to experiment with t_e and t_g to find the best values for a given region of a spectrum. Because instrumental effects such as field inhomogeneity make experimental line shapes non-Lorentzian, resolution enhancement is best combined with reference deconvolution. **Figure 3** shows the application of Lorentz–Gauss resolution enhancement to a proton multiplet.

Even where neither sensitivity nor resolution enhancement is sought, time-domain weighting is desirable where some NMR signal survives at the end of the sampled data. Such a truncated dataset is equivalent to the full, untruncated signal multiplied by a window function; the convolution theorem shows that the resultant spectrum will contain the true line shapes convoluted by a ‘sinc’ $[\sin(x)/x]$ function, giving rise to ‘wiggles’ on either side of lines. Applying a weighting function $W(t)$, which brings the time-domain data smoothly to zero (‘apodization’), can reduce or suppress such undesirable artefacts.

Figure 3 Expansions of the multiplet at 5.1 ppm in the 400 MHz proton spectrum of geraniol in deuteriomethanol: (a) raw spectrum; and (b) spectrum after Lorentz–Gauss conversion using rising exponential weighting with a time constant of $1/\pi s$ and Gaussian weighting with a time constant of 1 s.

Most NMR spectra are presented in phase-sensitive mode, but this is not appropriate where the phases of signals vary rapidly or unpredictably with position, as in some magnetic resonance imaging and multidimensional NMR experiments. The modulus of a complex Lorentzian line shape shows a very broad base because of the contribution from the (imaginary) dispersion mode component. This can be suppressed if time-domain weighting is used to force the experimental signal into a form that is time-symmetric, for example using the function $W(t)$ above with a small t_e (‘pseudo-echo’ weighting) or using a half sine-wave (‘sine-bell’ weighting). Although it is common to arrange for such weighting to leave the maximum of the weighted signal at the midpoint of the experimental data, this is neither necessary nor always desirable. Absolute value mode presentation is the norm where phase cycling or pulsed field gradients are used to produce signal phase modulated as a function of t_1 in 2D NMR; it is to be avoided where possible because overlapping peaks are distorted by interference between their dispersion mode parts.

Fourier Transformation

The classical frequency domain spectrum $S(\nu)$ is the Fourier transform of the FID $s(t)$:

$$S(\nu) = \int_0^{t_a} s(t) \exp(-2\pi i \nu t) dt \quad [4]$$

where the integration limits reflect the fact that the FID starts at time zero and is recorded for a time t_a . Practical spectrometers use digital technology, so the FID $s(t)$ is digitized at regular intervals Δt to give a time series of M points $s_k = s[(k-1)\Delta t]$, where $(M-1)\Delta t = t_a$, and a discrete Fourier transform (DFT) is carried out using the Cooley–Tukey FFT algorithm. The DFT of a time series of N complex points with spacing Δt generates a frequency spectrum which is a series of N complex points with spacing $1/(N\Delta t)$ Hz:

$$S_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} s_k \exp(-2\pi i kn/N) \quad [5]$$

where the frequency of the n th point is $(n-1)/(N\Delta t)$ Hz. Both the continuous and the discrete Fourier transform can use several different sign and normalization conventions; those given here are widely used, but others are equally valid. Spectrometers are almost invariably restricted by the FFT to Fourier transforming numbers of points N which are powers of 2.

Discrete sampling in the time domain introduces an ambiguity into the frequency domain: signals at frequencies separated by multiples of $1/(\Delta t)$ Hz are indistinguishable,

since their relative phases only change by multiples of 2π between sampling points. NMR signals which lie outside the range 0 to $(N-1)/(N\Delta t)$ will be 'aliased' by adding or subtracting the spectral width $1/\Delta t$ until they lie within this window, as seen in **Figure 4**. Since the signals that emerge from the spectrometer receiver may have positive or negative frequencies, the output of the DFT needs to be rotated by $N/2$ points [$1/(2\Delta t)$ Hz] so that the digitized spectrum covers the range $-1/(2\Delta t)$ to $(N/2-1)/(N\Delta t)$ Hz. By convention, the resultant spectrum is plotted with frequency increasing from right to left, so that the most shielded nuclei (those with lowest chemical shift) lie at the right. Some older spectrometers sample the real and imaginary receiver channels alternately rather than simultaneously, using a real rather than a complex Fourier transform; signals outside the spectral width then 'fold' back into the spectrum by reflection about the frequency limits $\pm 1/(2\Delta t)$.

Phasing

The measurement of NMR data must wait until the radiofrequency pulse and its after-effects have died away, which can take several tens of microseconds; analogue or digital filtration also delays the arrival of the NMR signal at the receiver output. The effect on an NMR signal of a delay time δ is to add a phase shift $\exp(2\pi i\nu\delta)$ to a signal of frequency ν , causing the signal phase to vary linearly across the spectrum. In addition, the relative phases of the receiver reference signals and the transmitter pulse

are arbitrary, so both a zeroth- and a first-order phase correction are needed to bring all signals into absorption mode. The phased spectrum $S_p(\nu)$ can be written as:

$$S_p(\nu) = S(\nu) \exp[-i(\phi_0 + \phi_1 \nu \Delta t)] \quad [6]$$

where the zeroth-order and first-order phase shifts ϕ_0 and ϕ_1 are normally determined either automatically, or by the spectrometer operator using an interactive display. **Figure 5** shows a typical spectrum before and after phasing.

First-order phase correction has one insidious effect, baseline distortion. A frequency-dependent phase shift cannot make up for the data that were lost during δ ; the baseline error is just the DFT of the missing data. However, provided δ is small compared to Δt , this baseline curvature can easily be corrected during post-processing of the spectrum. In 2D NMR, there will be different time delays δ_1 and δ_2 in the two time dimensions; phasing again is normally carried out using an interactive display.

Linear Prediction

A FID and its Fourier transform contain exactly the same information, but sometimes this is insufficient to give a readily interpretable spectrum. Where there is adequate internal evidence within the FID, it may be possible to extrapolate the NMR signals forwards and/or backwards in time to synthesize missing data and hence create a

Figure 4 75.4 MHz proton-decoupled ^{13}C spectra of 30% menthol in deuteriochloroform, (a) recorded with all signals within the spectral window, and (b)–(d) with the transmitter displaced to high field in 500 Hz steps. Spectra (c) and (d) show the aliasing of the high-field signals to reappear at the low-field end of the spectrum.

Figure 5 75.4 MHz proton-decoupled ^{13}C Spectra of 30% menthol in deuteriochloroform, (a) before and (b) after zeroth- and first-order phase correction.

time-domain signal that transforms to a clearer spectrum. The two commonest uses of such an extrapolation are backwards in time to replace data lost during the time δ , and forwards in time to improve resolution. A typical digitized experimental FID contains a series of n exponentially damped, complex signals, plus a background of random noise. The NMR signal can be written as:

$$s_k = \sum_{j=1}^n \alpha_j \beta_j^k \quad [7]$$

where the complex number $\alpha_j = A_j \exp(i\phi_j)$ defines the phase ϕ_j and amplitude A_j of the j th signal, and $\beta_j = \exp(2\pi i \Delta t \nu_j) \exp(-\Delta t/T_j)$ is determined by the frequency ν_j and decay constant T_j . The contribution made by component j to point s_k is just the contribution to s_{k-1} multiplied by β_j . Linear prediction (LP) algorithms take a FID of M points and fit this time series with a set of m complex coefficients a_j

$$s_k = \sum_{j=1}^m a_j s_{k-j} \quad [8]$$

so that point k is expressed as a linear combination of the previous m points (forward prediction), or of the subsequent m points (backward prediction)

$$s_k = \sum_{j=1}^m a_j s_{k+j} \quad [9]$$

A variety of algorithms exist for finding the coefficients a_j and multipliers β_j with which the experimental data can

be extrapolated forwards or backwards; all share some common problems. Linear prediction has difficulty distinguishing between positive and negative decay constants T_j , and so is best suited to time series in which all the decay constants are either positive or negative, allowing spurious β values to be rejected. The number m of coefficients a_j to be used has to be decided by the experimenter: too few, and peaks will be missed; too many and noise will be treated as signal. NonLorentzian line shapes make exponential damping a poor approximation, increasing the number of coefficients needed.

Linear prediction is (despite its name) a nonlinear method and can produce very misleading results, but with care it can greatly ease interpretation of poorly digitized spectra. It is particularly useful in 2D NMR, where signals are routinely truncated in the t_1 dimension.

Maximum Entropy Reconstruction

Although linear prediction can be used to extract spectral data directly from a FID ('parametric LP'), it is commonly used to extrapolate the experimental time-domain data, which are then weighted and transformed as normal. Maximum entropy reconstruction, in contrast, seeks to fit the experimental FID with a model function that contains the minimum amount of information consistent with fitting experiment to within the estimated noise level. The criterion of minimum information corresponds to the maximum Shannon informational entropy $S(p)$, which for a probability

distribution p is defined as

$$S(p) = - \sum_n p_n \log_e p_n \quad [10]$$

Maximum entropy methods have generated considerable controversy; they have been described (a little unkindly) as generating more heat than light. Their results can show spectacular improvements in signal-to-noise ratio, but this should not be confused with sensitivity of detection. Maximum entropy methods successfully pick out those signals that are above a defined threshold, but miss those below it; the signal amplitude estimates produced are comparable to those obtainable by simply fitting a model line shape to the Fourier transform spectrum. Thus for well-sampled experimental data the advantages of maximum entropy methods are largely cosmetic, and come at a high computational cost. Where such methods can be very valuable is with data sets that are damaged, incomplete, not sampled at uniform time intervals, or require deconvolution.

Postprocessing Techniques

The simplest and most widely used form of postprocessing is integration of the signal intensity. The integral of a resonance is proportional to the number of spins contributing to it; thus the relative numbers of nuclei in different chemical groupings can be found by comparing the integrals of their signals under appropriate experimental conditions. Accurate integration almost always requires operator intervention to carry out baseline correction, varying according to need from simple offset and slope correction through to the subtraction of a baseline calculated by spline or polynomial fit to operator-defined regions of empty baseline.

A second common example of postprocessing is the listing of signal heights and positions ('peak picking'), for the measurement of chemical shifts and coupling constants, or as the first step in the extraction of parameters such as relaxation times, rate constants or diffusion coefficients. In principle, the integral of a signal should give a better estimate of signal amplitude than peak height, being independent of line shape; in practice, baseline errors and signal overlap mean that peak height measurements are usually preferred for intensity comparisons between corresponding signals in different spectra.

Where signals overlap, neither integration nor peak picking gives accurate signal intensities. Here iterative fitting can be used to decompose the experimental spectrum into contributions from individual lines, typically assumed to have Lorentzian or Gaussian shapes; the positions, amplitudes and widths of the theoretical line shapes are varied to minimize the sum of the squares of the differences between the experimental and calculated

spectra. Such least-squares fitting is easily perturbed by instrumental distortion of the line shapes, for example as a result of static field inhomogeneity, so the best results require either great care with shimming or some form of compensation for instrumental line shape contributions.

One effective way to compensate for many instrumental sources of error is reference deconvolution. Since most instrumental errors (e.g. static field inhomogeneity and magnetic field instability) affect all signals equally, multiplying the experimental FID by the complex ratio of the theoretical and experimental signals for a reference resonance leads to a spectrum in which such errors have been corrected. This technique can be used to ensure that all lines are basically Lorentzian, and also to enforce strict comparability between different spectra in a series, for example to correct t_1 noise in multidimensional NMR.

Many other data processing techniques are used to extract useful information from experimental NMR spectra. Signal intensities compiled by peak picking may be fitted to an exponential or Gaussian function, as in the determination of relaxation times and in pulsed field gradient spin-echo measurements of diffusion coefficients. The latter experiment can be extended to the construction of a pseudo-2D spectrum in which signals are dispersed according to chemical shift in one dimension and diffusion coefficient in the other ('diffusion-ordered spectroscopy'). In many spectra the extraction of chemical shift and coupling constant values is hindered by second-order effects ('strong coupling'); the analysis of strongly coupled spectra is most effectively carried out using quantum-mechanical simulation. This can be partially automated in favourable cases, the experimental spectrum being used as a target for least-squares fitting in which the variable parameters are the chemical shifts and coupling constants rather than simply the signal positions, amplitudes and widths. The extraction of kinetic parameters from exchange-broadened band shapes ('line shape analysis') can be similarly automated.

Fast multi-dimensional methods

Recent methods for speeding up multidimensional NMR experiments by modifying the normal time-domain sampling protocols have gained popularity. These all have data processing implications. These new schemes include the filter diagonalization method, a single-scan 2D technique, Hadamard spectroscopy, and a proposal based on projection-reconstruction of 3D spectra. All these methods can provide marked improvements in the total data acquisition time.

If a priori knowledge exists as to which frequencies need to be measured, this can be used to speed up spectral acquisition by measuring only those frequencies

of interest using Hadamard encoding. In Hadamard spectroscopy, the evolution time in the indirect dimension is replaced by phase-modulated multi-site frequency selective excitation. Recent applications of Hadamard-encoded NMR spectroscopy have shown increased time resolution resulting from very fast spectral acquisition, while maintaining the spectroscopic resolution associated with 2D spectra. Specific examples include measurement of proton-deuteron exchange kinetics and frequency-resolved diffusion and relaxation measurements of chemically similar species in mixtures. The use of Hadamard encoded filters to measure methyl–methyl cross-relaxation has also been demonstrated.

Kupce and Freeman have shown that limited radial sampling of spin evolution space, followed by the use of projection–reconstruction methods can achieve the same result as full sampling of a multidimensional experiment and that it reduces the measurement time by many orders of magnitude. They define hyperdimensional NMR as a technique that derives all possible direct and indirect correlation spectra from a limited set of low-dimensional measurements, as opposed to the conventional method where all correlations are measured directly.

Frydman and co-workers have pioneered a method enabling the acquisition of complete 2D NMR data sets within a single continuous acquisition, thus in principle shortening the acquisition time of multidimensional NMR experiments by several orders of magnitude. This approach is compatible with existing multidimensional pulse sequences (e.g. COSY, TOCSY, HSQC, and MRI) and can be implemented using conventional hardware. The principle used is spatial encoding of the NMR interactions in the indirect dimension, generating the various required time incremented data from different parts of the sample.

The high repetition rates that become possible allow improved studies of reaction kinetics and this has been exemplified by fast HMQC NMR spectroscopy, a spatially encoded and relaxation-optimized approach that can provide 2D protein correlation spectra at around a 1 s repetition rate for samples in the low millimolar concentration range. This has allowed a study of the fast hydrogen-deuterium exchange amide sites in ubiquitin.

Typical acquisition times for 2D NMR spectra range from minutes to hours, so hyperpolarization techniques have been explored to boost the NMR sensitivity, including an *ex situ* dynamic nuclear polarization method. Although this methodology is able to boost the sensitivity by orders of magnitude, it is necessary to acquire the 2D spectrum in one or a few scans since the loss of hyperpolarization is rapid. Thus, dynamic nuclear polarization approach has been combined with the above methods of spatially encoded ultrafast NMR spectroscopy, yielding 2D NMR spectra of liquid samples at submicromolar concentrations in around 0.1 s.

Diffusion-ordered spectroscopy

Diffusion-ordered spectroscopy (DOSY) separates the NMR signals of different species according to their diffusion coefficient. The signals from each substance in a mixture decay at the same rate, dependent on its diffusion coefficient, as the gradient strength increases, constructing a bilinear NMR data set. By calculating the diffusion coefficient for each component, it is possible to obtain a 2D NMR spectrum: one dimension is the conventional chemical shift and the other is the diffusion coefficient. A series of spectra is measured with different pulsed field gradient strengths, and the signal decays are analysed to extract a set of diffusion coefficients with which to synthesize the diffusion domain of a DOSY spectrum. In 2D DOSY the initial diffusion-weighted spectra are 1D; adding diffusion weighting to 2D experiments such as COSY, NOESY or HMQC gives 3D DOSY spectra. The difficulty of extracting accurate and meaningful diffusion parameters from overlapping signal decays sets strict limits on the diffusion resolution. To identify small differences reliably, it is necessary that the systematic errors be reduced to an absolute minimum. The challenge of designing successful high-resolution DOSY techniques is to combine experimental methods which minimize such errors with data analysis procedures which compensate as accurately as possible for the errors that remain.

Potential applications of DOSY NMR include identification of the components and impurities in complex mixtures, such as body fluids, or reaction mixtures, and technical or commercial products, for example, comprising polymers or surfactants.

Data processing is an important step to interpret DOSY NMR. Univariate and multivariate methods have been used for the data processing but all of them have difficulties when applied to real-world cases. The big challenge appears when dealing with more complex samples, for example, components with small differences in diffusion coefficients, or severe overlap in the chemical shift dimension. Two single-channel methods, including SPLMOD and continuous diffusion coefficient (CONTIN), and two multivariate methods, called direct exponential curve resolution algorithm (DECRA) and multivariate curve resolution (MCR), have been investigated.

Most recently the potential of pure shift methods, in which the effects of scalar couplings are suppressed have been investigated, so that the multiplet structure normally encountered in proton NMR is collapsed, to provide a major improvement in the resolution of proton DOSY experiments.

Statistical spectroscopy

The implementation of an approach known as statistical total correlation spectroscopy (STOCSY) for aiding the

identification of the various NMR peaks from a given molecule of potential biomarker interest in complex biochemical mixtures has been a recent development. STOCSY takes advantage of the multi-collinearity of the intensity variables in a set of 1D spectra (e.g. ^1H NMR spectra) to generate a pseudo-2D NMR spectrum that displays the correlation among the intensities of the various peaks across the whole sample. This method is not limited to the usual connectivities that are deducible from more standard 2D NMR spectroscopic methods, such as TOCSY and is hence applicable to singlets or to peaks that are from functional groups far apart in the molecule.

In a related manner covariance NMR has been developed - this is a true 2D NMR representation and is an alternative to homonuclear 2D Fourier transform NMR. However, it produces symmetric spectra with the spectral resolution solely determined by the sampling, apodization, and processing along the detection dimension. The naturally high resolution along the indirect dimension allows a reduction in the number of increments and hence saving of NMR measurement time. Covariance NMR processing was originally available as downloadable software, but now can be accessed via a web portal. This operates in an integrated manner, with the first part of the web portal accepting 2D NMR spectra of complex mixtures such as from biofluids or cell extracts as input, and the second part returning spectra of individual components of the mixture. In the third step, the web query part of the web portal screens the returned traces against NMR spectral databases. The three parts of

the portal can be used together or separately, depending on the specific needs.

Symbols

<i>a, b, c</i>	molecule-fixed principal axes
B_0	applied magnetic field
D_{ij}	dipolar spin–spin coupling
h	Planck constant
$\mathcal{H}$	Hamiltonian
I	nuclear spin quantum number
I_i	spin angular momentum operator
I_{zi}	component of I_i along Z
J_{ij}	electron-mediated spin–spin coupling
k_B	Boltzmann constant
n_i	director (unit vector at point i)
$P_{LC}(\beta, \gamma)$	probability that director angle is in $\beta + d\beta$, $\gamma + d\gamma$
$P(n)$	probability of configuration n
Q_N	nuclear quadrupole moment
r, s, t	lattice-fixed principal axes
r_{ij}	internuclear vector
$S_{\alpha\alpha}$	Saupe order parameters
T	temperature
$T_{B,q}$	component of q th interaction along B_0
T_q	interaction tensor
$T_{\alpha\beta,q}$	component of q th interaction with respect to molecule fixed axes α and β
U_{ext}	potential of mean torque
V_i	electric field gradient at site i
x, y, z	molecular axes
γ_i	magnetogyric ratio of i th nucleus
θ_i	angle of B_0 with axis i
μ	nuclear magnetic dipole moment
μ_0	permeability of free space
σ	shielding constant
ϕ	angle of rotation about bond
χ	magnetic susceptibility

The simplest anisotropic system is a single crystal and in this case the spin interactions depend upon the orientation of the molecules with respect to the direction of the applied magnetic field, B_0 , of the spectrometer. The anisotropies of the various interactions that affect the spectrum can be measured by changing the orientation of the crystal in the field. The spin interactions in polycrystalline or noncrystalline solids are still anisotropic, but now the spectra are invariant to sample orientation. Molecular motion can have a dramatic effect on the

NMR spectra observed for anisotropic systems, and characterizing such motion is one of the principal uses of this spectroscopy.

The most complex anisotropic systems are the various liquid crystalline phases; now the molecular motion is similar to that in a normal, isotropic liquid in that there is rapid rotation and diffusion of the molecules. These phases differ from isotropic phases in that the motion is not random, and this has a profound affect on their NMR spectra.

The spectra produced by anisotropic systems are more complex than those from isotropic phases, but they contain more information. However, the spectral complexity is often too great for all the information to be obtained, and for solid samples it is usually preferable to dissolve the material in order to simplify the spectrum. Various other methods have been developed that enable some, if not all, of the information to be extracted from the NMR spectrum of an anisotropic sample, and these are described elsewhere. The aim of this article is to show what can, in principle, be obtained by a successful analysis of the NMR spectra obtained from solid and liquid crystalline samples.

General Considerations

We will consider only experiments that use a strong magnetic field, that is those using mainstream spectrometers in which B_0 is greater than about one tesla. In this case, for nuclei with spin $I = \frac{1}{2}$, the largest magnetic interaction is that between μ , the magnetic dipole moment of the nucleus, and the field, the Zeeman interaction. This leads to the field direction being, to a good approximation, a unique axis of quantization for the nuclear spins; and the experiments yield only the component, $T_{B,q}$, of the q th interaction along B_0 , and so these are the parameters that may be obtained from the spectra. For nuclei with $I > \frac{1}{2}$, the interaction of the nuclear electric quadrupole moment, eQ_N , of a nucleus of isotopic species denoted by N with the electric field gradient, V_i , at the site i may be larger than the Zeeman interaction, and the spins will no longer be quantized along B_0 . We will not deal with this situation, and the interested reader is referred to the article on the theory of nuclear quadrupole resonance. The present discussion is therefore confined to spin $\frac{1}{2}$ nuclei, or to those with

small quadrupole moments, or at sites of small field gradients, such that the Zeeman term still dominates the nuclear spin Hamiltonian.

For each of the spin interactions that affect the spectrum of an anisotropic sample, the value of $T_{B,q}$ may have both a part, $T_{B,q}(\text{isotropic})$, that is independent of the orientation with respect to B_0 of the molecule containing the spin, and a part, $T_{B,q}(\text{anisotropic})$, that is orientation dependent. Thus,

$$T_{B,q} = T_{B,q}(\text{isotropic}) + T_{B,q}(\text{anisotropic}) \quad [23]$$

Four interactions may affect the spectrum of an anisotropic sample. The shielding (or chemical shift), σ_i , of the nucleus at a site i always has a finite value of $T_{B,q}(\text{isotropic})$, σ_i^0 , in an anisotropic sample. There will be a nonvanishing contribution $T_{B,q}(\text{anisotropic}) = \sigma_i^a$ provided that the symmetry of the site i is lower than tetrahedral. The electron-mediated spin-spin coupling, J_{ij} , between a pair of nuclei in an anisotropic sample will also in general have two nonvanishing contributions, J_{ij}^0 and J_{ij}^a . Both terms are negligible when the two nuclei are in different molecules. For nuclei within one molecule, the anisotropic term ranges from being negligible to being very large depending on the nuclear isotopes involved. The dipolar spin-spin coupling, D_{ij} , has only an anisotropic term, as does the quadrupolar coupling, $eQ_N V_i$. We will return to the individual anisotropic interactions after discussing the features they have in common.

Relationship between Spectral Parameters $T_{B,q}$ and Molecular Properties

To understand what information is provided on properties of the molecules, we need to know how to relate $T_{B,q}$ to components $T_{\alpha\beta,q}$ of the q th interaction in a reference frame fixed within a molecule. This relationship is a general one since all four interactions are second-rank tensors, and so:

$$T_{B,q} = \sum_{\alpha\beta} T_{\alpha\beta,q} \cos \theta_\alpha \cos \theta_\beta \quad [2]$$

$T_{\alpha\beta,q}$ is a component in the (xyz) molecular axes, and θ_α is the angle B_0 makes with the axis α . There are nine components of $T_{\alpha\beta,q}$:

$$\begin{array}{ccc} T_{xx,q} & T_{xy,q} & T_{xz,q} \\ T_{yx,q} & T_{yy,q} & T_{yz,q} \\ T_{zx,q} & T_{zy,q} & T_{zz,q} \end{array}$$

The sum $T_{xx,q} + T_{yy,q} + T_{zz,q}$ is independent of the choice of the axes. For some systems $T_{\alpha\beta,q} \neq T_{\beta\alpha,q}$ (for a discussion, see the paper of Smith, Palke and Gerig listed in Further Reading), but the effect of this asymmetry can

usually be neglected, and in this case there is a special set of axes (abc) such that only the diagonal elements are nonzero. These are known as the principal axes of the interaction tensor and the $T_{aa,q}$, $T_{bb,q}$ and $T_{cc,q}$ are principal components of T_q . It is important to note that the different interactions will not usually share a common set of principal axes. In principal axes, eqn [2] is simplified to

$$T_{B,q} = T_{aa,q} \cos^2 \theta_a + T_{bb,q} \cos^2 \theta_b + T_{cc,q} \cos^2 \theta_c \quad [3]$$

There are obvious advantages in using principal axes, but their location in a molecule is not always known. This does not prevent us from working in principal axes when doing algebraic manipulations on eqn [2]. Thus, eqn [3] might seem inconsistent with eqn [1], but that this is not so can easily be appreciated by replacing $\cos^2 \theta_\alpha$ by $(1 - \sin^2 \theta_\alpha)$ to give

$$\begin{aligned} T_{B,q} = & T_{aa,q} + T_{bb,q} + T_{cc,q} - T_{aa,q} \sin^2 \theta_a \\ & - T_{bb,q} \sin^2 \theta_b - T_{cc,q} \sin^2 \theta_c \end{aligned} \quad [4]$$

There is, however, a more useful way of expressing $T_{B,q}$ as a scalar plus an anisotropic part, and this is derived by noting that when the molecules move rapidly and randomly, as in an isotropic liquid or gas, $T_{B,q}$ is averaged (denoted by the brackets $\langle \rangle$) to produce $\langle T_{B,q} \rangle_{\text{iso}}$:

$$\langle T_{B,q} \rangle_{\text{iso}} = \sum_{\alpha,\beta} T_{\alpha\beta,q} \langle \cos \theta_\alpha \cos \theta_\beta \rangle \quad [5]$$

Using principal axes, and noting that $\langle \cos^2 \theta_\alpha \rangle = \frac{1}{3}$

$$\langle T_{B,q} \rangle_{\text{iso}} = \frac{1}{3} (T_{aa,q} + T_{bb,q} + T_{cc,q}) = T_q^0 \quad [6]$$

Remembering that the sum of the diagonal elements of T_q is independent of the axes, then we can see that eqn [6] is true for all choices of molecular axes even though we derived it in principal axes. Rearranging eqn [3] as

$$T_{B,q} = T_q^0 + \sum_{\alpha} T_{\alpha\alpha,q} \left(\cos^2 \theta_\alpha - \frac{1}{3} \right) \quad [7]$$

which leads to

$$T_{B,q} = T_q^0 + \frac{2}{3} \sum_{\alpha} T_{\alpha\alpha,q} (3 \cos^2 \theta_\alpha - 1) / 2 \quad [8]$$

Rearranging gives

$$\begin{aligned} T_{B,q} = & T_q^0 + \frac{2}{3} \left[T_{aa,q} - \frac{1}{2} (T_{bb,q} + T_{cc,q}) \right] (3 \cos^2 \theta_a - 1) / 2 \\ & + \frac{1}{2} (T_{bb,q} - T_{cc,q}) (\cos^2 \theta_b - \cos^2 \theta_c) \end{aligned} \quad [9]$$

Equation [9] has the advantage of showing clearly what happens if the tensor T_q is axially symmetric in the molecular principal axes, that is, when $T_{bb,q} = T_{cc,q}$.

Effect of Molecular Motion on the Interactions in Anisotropic Systems

We have already seen that rapid, random motion averages $T_{B,q}(\text{anisotropic})$ to zero, but what is the effect of motion that is rapid but not random? The definition of rapid is that the rate of the motion is much greater than the magnitude of $T_{B,q}(\text{anisotropic})$. Slower motion will contribute to the relaxation rates and is not discussed here. The effect of motion is to produce $\langle T_{B,q} \rangle$, an averaged value of $T_{B,q}$, which can be thought of as a sum of contributions, $T_{B,q}(n)$ from n configurations of the system, each with a normalized probability $P(n)$:

$$\langle T_{B,q} \rangle = \sum_n P(n) [T_q^0(n)(\text{isotropic}) + T_{B,q}(n)(\text{anisotropic})] \quad [10]$$

For most systems the isotropic contribution will not have a strong dependence on n , and so we will concentrate on the averaging of the anisotropic term.

For solids it is better to consider the different kinds of motion that occur, and to see how they affect the averages.

Rotation of whole, rigid molecules on lattice sites in crystals

Rotation about an n -fold axis, or hopping between n equivalent sites, produces an averaged tensor, one of whose principal axes, r , lies along the rotation axis. The location of the other two principal axes, s and t , will be in the plane orthogonal to r , and they are fixed with respect to the lattice and not the molecules. Thus,

$$\begin{aligned} \langle T_{B,q} \rangle &= \langle T_q^0 \rangle \\ &+ \frac{2}{3} \left[T_{rr,q} - \frac{1}{2} (T_{ss,q} + T_{tt,q}) \right] (3 \cos^2 \theta_r - 1)/2 \\ &+ \frac{1}{2} (T_{ss,q} - T_{tt,q}) (\cos^2 \theta_s - \cos^2 \theta_t) \end{aligned} \quad [11]$$

The relationship between $T_{rr,q}$ and the components of T_q in the (abc) principal frame is given by

$$T_{rr,q} = T_{aa,q} \cos^2 \theta_{ar} + T_{bb,q} \cos^2 \theta_{br} + T_{cc,q} \cos^2 \theta_{cr} \quad [12]$$

The angles θ_{ar} , θ_{br} and θ_{cr} are between the axes a , b , c and r . For two-site hopping, the location of s and t will depend upon the structure of the molecule.

When $n \geq 3$, the averaged tensor is axially symmetric about r so that eqn [11] simplifies to

$$\begin{aligned} \langle T_{B,q} \rangle &= \langle T_q^0 \rangle + \frac{2}{3} \left[T_{rr,q} - \frac{1}{2} (T_{ss,q} + T_{tt,q}) \right] \\ &\times (3 \cos^2 \theta_r - 1)/2 \end{aligned} \quad [13]$$

and $T_{rr,q}$ and $\frac{1}{2}(T_{ss,q} + T_{tt,q})$ can be replaced by $T_{\parallel r,q}$ and $T_{\perp r,q}$.

These relationships apply to all the spin interactions when the molecule rotates as a whole because in this case the internuclear distances within a molecule do not change.

Rotation of a group of nuclei within a molecule

The values of $\langle T_{B,q} \rangle$ for interactions involving nuclei only in the group that is moving relative to the crystal lattice (and hence relative to B_0) are affected in the same way as described for whole-molecule rotation except that now the axes s and t are fixed in the nonrotating part of the molecule. The spin-spin interactions between nuclei in the rigid and moving parts of the molecules will be averaged in a way that depends on the structure of the molecules.

Hopping (diffusion) of molecules between lattice sites

This kind of motion will usually occur in combination either with whole-molecule rotation on a lattice site or with internal motion in the molecules. The diffusion process will have a large effect on dipolar interactions between nuclei in different molecules. The exact magnitude of the effect will depend on the crystal structure, but it will always lead to a reduction in the intermolecular contribution to dipolar coupling.

Molecular motion in liquid crystalline samples

In liquid crystalline samples the molecules rotate and diffuse rapidly but not randomly. The diffusive motion means that the distance between nuclei in different molecules is changing, with the result that the intermolecular contribution to the dipolar coupling is zero. The averaging produced by the rotational motion of whole, rigid molecules depends to some extent on the nature of the phase and the effect on it of the magnetic field of the spectrometer. We will consider here the simplest case only, which is when there is axial symmetry about B_0 . With uniaxial symmetry the result for a rigid molecule is to average the angular factors in eqn [9], which is usually expressed in a slightly different way; thus

$$\begin{aligned} T_{B,q} &= T_q^0 + \frac{2}{3} \left[T_{aa,q} - \frac{1}{2} (T_{bb,q} + T_{cc,q}) \right] S_{aa}^B \\ &+ \frac{1}{3} (T_{bb,q} - T_{cc,q}) (S_{bb}^B - S_{cc}^B) \end{aligned} \quad [14]$$

where

$$S_{\alpha\alpha}^B = \langle 3 \cos^2 \theta_\alpha - 1 \rangle / 2 \quad [15]$$

where θ_α is the angle between B_0 and axis α . Note that now both the $T_{\alpha\alpha,q}$ and the $S_{\alpha\alpha}^B$ are unknown parameters

that may be obtained from an analysis of the NMR spectra, and that their absolute values cannot be obtained separately. In practice, for chemical shifts and quadrupolar coupling it is usually possible to use values of the $T_{\alpha\alpha,q}$ obtained from the spectrum of a single-crystal sample to determine the $S_{\alpha\alpha}^B$. For dipolar coupling it is necessary to assume just one internuclear distance in order to obtain the separate values of the $S_{\alpha\alpha}^B$ and the D_{ij} .

The relationship between the values of the $S_{\alpha\alpha}^B$ and the orientational order of the molecules in the liquid crystalline phase can be derived by first introducing the concept of a director, $\mathbf{n}_i$. This is a unit vector at point i in the sample which defines the preferred orientation of the anisotropically shaped molecules. This can be quantified by a function, $P_{LC}(\beta, \gamma)$, which describes the probability that the director makes angles between β and $\beta + d\beta$ and γ and $\gamma + d\gamma$ in a frame (abc) fixed in the molecules, as shown in **Figure 1**. This probability density function has a maximum when β is zero, whose magnitude grows towards a value of unity as the molecules become ordered by reducing temperature. The values of $\langle T_{B,q} \rangle$ can be thought of as arising from rapid motion of the molecules about the director giving an average, $\langle T_{n,q} \rangle$, of the T_q along $\mathbf{n}$, and then using the relationship

$$\langle T_{B,q} \rangle = \langle T_{n,q} \rangle (3 \cos^2 \theta_{Bn} - 1) / 2 \quad [16]$$

where θ_{Bn} is the angle between $\mathbf{n}_i$ and $\mathbf{B}$. If the directors are distributed relative to $\mathbf{B}_0$ then the spectrum will be a sum of spectra and will be like that from a polycrystalline

Figure 1 Angles defining the orientation of the magnetic field, $\mathbf{B}_0$, in axes (abc) fixed in a molecule.

powder. The averages $\langle T_{n,q} \rangle$ are given by

$$\begin{aligned} \langle T_{n,q} \rangle = T_q^0 + \frac{2}{3} \left[T_{aa,q} - \frac{1}{2} (T_{bb,q} + T_{cc,q}) \right] S_{aa} \\ + \frac{1}{3} (T_{bb,q} - T_{cc,q}) (S_{bb} - S_{cc}) \end{aligned} \quad [17]$$

where the $S_{\alpha\alpha}$ are known as Saupe order parameters. They are defined as

$$S_{aa} = \int \frac{1}{2} (3 \cos^2 \beta - 1) P_{LC}(\beta, \gamma) \sin \beta d\beta \quad [18]$$

$$S_{bb} - S_{cc} = \frac{3}{2} \int \sin^2 \beta \cos 2\gamma P_{LC}(\beta, \gamma) \sin \beta d\beta d\gamma \quad [19]$$

The important point to note is that they can act as tests for models of $P_{LC}(\beta, \gamma)$. This function can be used to define an effective orienting potential, or potential of mean torque, $U_{\text{ext}}(\beta, \gamma)$, thus

$$P_{LC}(\beta, \gamma) = Z^{-1} \exp[-U_{\text{ext}}(\beta, \gamma) / k_B T] \quad [20]$$

with

$$Z = \int \exp[-U_{\text{ext}}(\beta, \gamma) / k_B T] \sin \beta d\beta d\gamma \quad [21]$$

where T = temperature and k_B = Boltzmann constant.

In the absence of a magnetic field, the directors vary in orientation relative to some space-fixed axes in a completely random way. The directors may, however, be aligned uniformly by a magnetic field. If the molecules comprising the liquid crystal phase have a positive anisotropy, $\Delta\chi$, in their magnetic susceptibility, then the directors align parallel to the field, so that θ_{Bn} is 0, and $\langle T_{B,q} \rangle = \langle T_{n,q} \rangle$. If $\Delta\chi$ is negative, the directors align in a plane perpendicular to the field, making $\theta_{Bn} = 90^\circ$ and $\langle T_{B,q} \rangle = -\frac{1}{2} \langle T_{n,q} \rangle$. In both cases the spectra are like those for a single crystal except the lines are much narrower because of the absence of broadening from intermolecular effects.

The effect of internal motion on $\langle T_{n,q} \rangle$ for liquid crystalline samples

Fast internal motion produces an additional averaging of the $T_{n,q}$ in a similar way to the case of solid samples, but with the very important difference that there is a co-operative effect of changes in molecular shape and orientational order. For example, consider rotation about a bond through an angle ϕ . The probability distribution becomes dependent on ϕ as well as on β and γ , and so too does the mean potential energy of the molecules in the phase. Thus, we revise eqns [20] and [21] to

$$P_{LC}(\beta, \gamma, \phi) = Z^{-1} \exp[-U(\beta, \gamma, \phi) / k_B T] \quad [22]$$

$$Z = \int \exp[-U(\beta, \gamma, \phi)/k_B T] \sin\beta \, d\beta \, d\gamma \, d\phi \quad [23]$$

The mean potential may be divided into a purely anisotropic part, $U_{\text{ext}}(\beta, \gamma, \phi)$, which vanishes in the isotropic phase, and a part, $U_{\text{int}}(\phi)$, which does not:

$$U(\beta, \gamma, \phi) = U_{\text{ext}}(\beta, \gamma, \phi) + U_{\text{int}}(\phi) \quad [24]$$

Because the potential of mean torque has become dependent on the internal motion, then so too do the order parameters; that is, eqns [18] and [19] become

$$S_{aa}(\phi) = \int \frac{1}{2} (3 \cos\beta - 1) P_{\text{LC}}(\beta, \gamma, \phi) \sin\beta \, d\beta \quad [25]$$

$$S_{bb}(\phi) - S_{cc}(\phi) = \frac{3}{2} \int \sin^2\beta \cos 2\gamma P_{\text{LC}}(\beta, \gamma, \phi) \times \sin\beta \, d\beta \, d\gamma \quad [26]$$

Various strategies have been suggested for obtaining $P_{\text{LC}}(\beta, \gamma, \phi)$ from observed values of $\langle T_{B,q} \rangle$.

Having obtained $P_{\text{LC}}(\beta, \gamma, \phi)$, it is then possible to determine $P_{\text{LC}}(\phi)$, the probability that the molecule in the liquid crystalline phase is in a conformation defined by the angle ϕ , as

$$P_{\text{LC}}(\phi) = \int P_{\text{LC}}(\beta, \gamma, \phi) \sin\beta \, d\beta \, d\gamma \\ = \frac{\int \exp[-U(\beta, \gamma, \phi)/k_B T] \sin\beta \, d\beta \, d\gamma}{\int \exp[-U(\beta, \gamma, \phi)/k_B T] \sin\beta \, d\beta \, d\gamma \, d\phi} \quad [27]$$

Note that in principle this differs from $P_{\text{iso}}(\phi)$, the conformational probability distribution for the molecule in the isotropic phase, which is

$$P_{\text{iso}}(\phi) = \frac{\exp[-U_{\text{iso}}(\phi)/k_B T]}{\int \exp[-U_{\text{iso}}(\phi)/k_B T] d\phi} \quad [28]$$

The Anisotropic Nuclear Spin Interactions

As noted earlier, we will confine our discussion to the case when the interaction of the spins with the magnetic field, the Zeeman interaction, is dominant so that the direction of the applied, static field determines the axis of quantization and the experiments yield the component $T_{B,q}$ of the various interactions in this direction. It is now convenient to define this as the Z direction. A very detailed discussion of the spin interactions, and their contribution to the nuclear spin Hamiltonian, has been given by Smith, Palke and Gerig.

The Zeeman Interaction

The contribution, $\mathcal{H}_{\text{Zeeman}}$, to the nuclear spin Hamiltonian, in units of hertz, has the form:

$$\mathcal{H}_{\text{Zeeman}} = -\frac{1}{2\pi} \sum_i \gamma_i (1 - \sigma_{ZZi}) B_0 I_{Zi} \quad [29]$$

where γ_i is the magnetogyric ratio of the i th nucleus, and I_{Zi} is the component along Z of the nuclear spin angular momentum operator, I_i . The important feature is that this Hamiltonian has an identical form in both isotropic and anisotropic systems, and hence the spectral consequences are exactly the same. That is, the resonance is shifted in energy depending on the electronic environment at the i th site. The difference between these two kinds of system lies in the contributions to σ_{ZZ} in the two situations. Thus for a rigid molecule, eqn [9] becomes

$$\sigma_{ZZ} = \sigma^0 + \frac{2}{3} \left[\sigma_{aai} - \frac{1}{2} (\sigma_{bbi} + \sigma_{cci}) \right] (3 \cos^2 \theta_{ia} - 1) / 2 \\ + \frac{1}{2} (\sigma_{bbi} - \sigma_{cci}) (\cos^2 \theta_{bi} - \cos^2 \theta_{ci}) \quad [30]$$

The isotropic term, σ^0 , is much greater than the anisotropic contribution, and so there is only a small ($\sim$ kHz) difference between the resonance frequency of a nucleus in an isotropic and anisotropic environment.

Note that the location of the principal axes (abc) depends on the site occupied in a molecule by the nucleus. The site symmetry in a rigid molecule determines whether $\sigma_{aai} = \sigma_{bbi} = \sigma_{cci}$ (isotropic site symmetry), $\sigma_{aai} \neq \sigma_{bbi} = \sigma_{cci}$ (axial site symmetry), or $\sigma_{aai} \neq \sigma_{bbi} \neq \sigma_{cci}$ (site asymmetry). The nature of the site symmetry is in fact revealed most clearly and easily by recording the spectra of polycrystalline samples, if possible. This is particularly true when the Zeeman term is the only one determining the observed spectrum. This situation can easily be realized, for example for ^{13}C , ^{15}N or ^{31}P nuclei.

Figure 2 shows the shape of spectra obtained for nuclei at sites of the three different symmetries.

Electron-Mediated Spin-Spin Coupling

The contribution to the Hamiltonian, in hertz, is

$$\mathcal{H}_J = \sum_{i < j} \left\{ J_{ij}^0 \left[I_{Zi} I_{Zj} + \frac{1}{2} (I_{+i} I_{-j} + I_{-i} I_{+j}) \right] \right. \\ \left. + J_{ij}^a \left[I_{Zi} I_{Zj} - \frac{1}{4} (I_{+i} I_{-j} + I_{-i} I_{+j}) \right] \right\} \quad [31]$$

$J_{ij}^0 (\equiv T_{B,q})$ (isotropic) in eqn [1]) is the scalar contribution to coupling, which is the only contribution in isotropic environments. J_{ij}^a is the anisotropic contribution, and its components in the principal, molecular frame can be obtained by substitution in eqn [9] for a rigid crystal, and eqn [14] for a rigid molecule in a liquid crystalline phase.

Figure 2 Spectra for a polycrystalline sample for nuclei with different site symmetries and subject only to the Zeeman interaction: (a) $\sigma_{aa} = \sigma_{bb} = \sigma_{cc}$; (b) $\sigma_{aa} = \sigma_{bb} > \sigma_{cc}$; (c) $\sigma_{aa} = \sigma_{bb} < \sigma_{cc}$; (d) $\sigma_{aa} \neq \sigma_{bb} \neq \sigma_{cc}$.

The operators I_{+i} and I_{-i} are defined as:

$$I_{+i} = I_{xi} + iI_{yi} \quad \text{and} \quad I_{-i} = I_{xi} - iI_{yi} \quad [32]$$

The magnitude of J_{ij}^a is predicted to be much smaller than either J_{ij}^0 or D_{ij} , the dipolar coupling between the same nuclei, when one of the nuclei is a proton. For other pairs of nuclei, J_{ij}^a may not be negligible. Values have been obtained experimentally from the spectra of molecules dissolved in liquid crystalline phases.

Dipolar Coupling

This is the through-space coupling between a pair of nuclear magnetic dipoles. It is a purely anisotropic interaction and is also symmetric about $\mathbf{r}_{ij}$, the inter-nuclear vector. It contributes a term to the Hamiltonian, in hertz, of

$$\mathcal{H}_D = \sum_{i < j} 2D_{ij} \left[I_{zi}I_{zj} - \frac{1}{4}(I_{+i}I_{-j} + I_{-i}I_{+j}) \right] \quad [33]$$

Note that this has identical spin operators to those involving J_{ij}^a in eqn [31]. This means that the spectra of anisotropic systems depend on $(2D_{ij} + J_{ij}^a)$, and that these two interactions cannot be determined separately from the spectra. For this reason, J_{ij}^a is often referred to a pseudo-dipolar coupling.

Dipolar coupling is axially symmetric about $\mathbf{r}_{ij}$ which is a principal axis, so that from eqn [9] there is just one

contribution to D_{ij} :

$$D_{ij} = D_{aaij}(3 \cos^2 \theta_{ij} - 1)/2 \quad [34]$$

where θ_{ij} is the angle between $\mathbf{r}_{ij}$ and $\mathbf{B}_0$. D_{aaij} for a fixed internuclear distance is given, in hertz, by

$$D_{aaij} = -[\mu_0 b \gamma_i \gamma_j / (16\pi^3)] / r_{ij}^3 \quad [35]$$

where $\mu_0 = 4\pi \times 10^{-7}$ and is the permeability of free space. This makes it possible to determine molecular structure from dipolar couplings.

The Quadrupolar Interaction

Remembering that we are restricting our discussion to the cases when the Zeeman term determines the axis of quantization of the nuclear spins, then the quadrupolar interaction contributes a term, in hertz, to the spin Hamiltonian of

$$\mathcal{H}_Q = \sum_i [eQ_N V_{ZZi} / (4bI_{Ni}(2I_{Ni} - 1))] \times [3I_{Zi}^2 - I_{Ni}(I_{Ni} + 1)] \quad [36]$$

where I_{Ni} is the nuclear spin quantum number of spin i of type N , which has quadrupolar moment eQ_N , and is at a site with an electric field gradient V_i . It is a purely anisotropic interaction, and so for a rigid molecule in a solid crystalline sample,

$$V_{ZZi} = V_{aai}(3 \cos^2 \theta_a - 1)/2 + \frac{1}{2}(V_{bbi} - V_{cci})(\cos^2 \theta_b - \cos^2 \theta_c) \quad [37]$$

ω	angular frequency of applied radiation/nuclear precession

Introduction

A microscope is generally regarded as an assembly of lenses used to give an image of small objects at high spatial resolution. By high spatial resolution is meant a resolution finer than can be resolved by the naked human eye, in other words better than 0.1 mm. The well-known ‘optical microscope’ uses either reflected or transmitted light to present an image and the resolution of this instrument is determined by the wavelength of the electromagnetic radiation, around 0.5 μm . There are many other forms of microscopy that use different radiations, such as the electron microscope, whose resolution is much finer because of the shorter wavelength of the electron beam, or the acoustic microscope which is very effective at probing near-surface properties using high-frequency sound waves. X-ray microscopes have been

developed in recent years, although these are rather tricky to use because of the need to generate relatively monochromatic soft X-rays that can then be focused by Fresnel lenses. This article describes a very different microscope, based on the use of radio waves, the so-called ‘nuclear magnetic resonance microscope’.

If one were to present the concept of a radio wave microscope in the context of our usual perspectives on such devices, three factors would emerge. First, one would expect that, like the X-ray microscope, the device would have excellent powers of penetration, since radio waves pass easily through most matter, excluding good conductors such as metals. Second, one would expect that it would be almost ideally noninvasive, because of the very low energy of the radiofrequency photon. In this regard it could be contrasted with electron microscopy and X-ray microscopy, which are both capable of breaking covalent bonds between atoms. Finally, it might be guessed that such a device would have hopelessly poor spatial resolution because of the very long wavelengths (several metres!) of the radiation.

This last point would be certain to render radio wave microscopy useless were it not for the phenomenon of nuclear precession exhibited by atomic nuclei with nonzero spin when placed in a magnetic field. This property means that those nuclei (the ‘spins’) have associated with them a special radio frequency that depends precisely on the local magnetic field strength, and if that magnetic field strength is varied from place to place in the sample, then the measurement of the frequency of each nucleus will indicate where its parent atom or molecule is positioned. By this means one could build up an image of the atomic distribution, avoiding altogether the normal wavelength (or ‘diffraction’) limit to resolution. The technique used to measure the spatially dependent spin precession frequency is nuclear magnetic resonance (NMR).

The prospects for such a method seem almost too good to be true, but there is an Achilles heel. NMR relies on the measurement of the nuclear frequency by means of the exchange of radiofrequency photons whose energies are so weak that they must compete with the thermal noise that exists in the detection circuitry. It is this latter effect that determines the ultimate resolution of such an instrument, and, using the best possible stable nucleus (the proton) in thermal equilibrium at room temperature,

and with a receiving antenna made from room-temperature metals, the limit is volume elements around $(10\text{ }\mu\text{m})^3$ for the image, an exceptionally poor resolution by comparison with all other microscopies. Indeed the NMR microscope is only just a microscope in the normal sense and one would hardly bother with it at all were it not for a few remarkably useful properties. It is exceptionally noninvasive as intimated earlier, and this makes it of special interest in *in vivo* biological applications. It is highly penetrating and can work perfectly well with optically opaque materials with minimal problems of ‘transparency’, and it is especially well suited to the study of liquid phases, a rather unusual property in the context of other microscopies. Most important of all, it enables the imaging of a number of molecular and atomic properties to which NMR is particularly suited. These include the local chemical composition, the local molecular order and rotational dynamics, and the local molecular translational motions. It is for these reasons that NMR microscopy, despite its rather poor spatial resolution, has found a number of important applications in science, technology and medicine.

Nuclear Magnetic Resonance Imaging

Proton NMR

Nuclear magnetic resonance was first detected in 1945, although its extension to imaging applications was to wait until 1973. NMR is an enormous field of research and the subject of very many textbooks in its own right. This article will attempt to give only a cursory introduction to the phenomenon, and the reader should look to some of the articles elsewhere in this Encyclopedia for further information. An isolated proton, when placed in a magnetic field, B_0 , occupies one of two quantum states with respect to the field direction and the quantum phases of those states rotate at the frequency $\omega = \gamma B_0$ (for example $\omega/2\pi = 300\text{ MHz}$ for a proton immersed in a 7 T field), where γ is the gyromagnetic ratio of the proton, the factor that determines the ratio of its magnetic properties to its spin properties. This phase rotation arises from the combined magnetic and spin properties of the nucleus and is known as precession. The proton has a very high value of γ (and hence radio-frequency photon energy) relative to other nuclei and it is highly abundant in most materials, as the nucleus of atomic hydrogen. It is thus the prime candidate for NMR microscopy.

In practice we deal with large ensembles of nuclei whose phases, in thermal equilibrium, are randomized so that the net magnetization presented by the sample is directed along B_0 , and results from the slight preponderance of spin-up over spin-down (typically around 1 in 10^5). Detection of the underlying precession

frequency therefore requires the intervention of a small, transverse, oscillatory magnetic field, B_1 (the so-called resonant radiofrequency field, generated by a coil surrounding the sample). This field is applied as a pulse for a finite duration t_p at the same frequency as the underlying precessional circulation, thus keeping its effect on the spins in step with their motion. As a result the spins gradually re-align themselves with respect to the combined effects of B_0 and B_1 , the result being a reorientation of the net magnetization vector to an angle $\gamma B_1 t_p$ with respect to B_0 . A ‘90°’ RF pulse would be one that left the magnetization precessing in the transverse plane. The same sample coil is used to excite the spin system from equilibrium (relaxation time T_1). Thus the NMR spectrometer consists of a magnetic field, a coil as antenna, and a radio transceiver. In the case of a microimaging system, an additional requirement is a set of magnetic field gradient coils. Typical NMR microscope RF coils and gradient coils are shown in **Figure 1**.

Position Encoding Using Field Gradients

The imaging principle is as follows. Suppose we now apply, in addition, a magnetic field gradient $\mathbf{G} = \nabla B_0$ (this can be achieved with specialized coil designs capable of generating quite uniform gradients along three orthogonal axes), then the precession frequency will depend on spin location and can be written

$$\omega = \gamma B_0 + \gamma \mathbf{G} \cdot \mathbf{r} \quad [1]$$

Because the receiver uses heterodyne phase-sensitive detection with reference frequency γB_0 , the additional term, $\gamma \mathbf{G} \cdot \mathbf{r}$, shows up as a difference oscillation, generally in the audiofrequency part of the spectrum. As a consequence, the heterodyne signal detected via the NMR coil at time t after the spins have precessed in the gradient has the mathematical form

$$S(\mathbf{k}) = \int \rho(\mathbf{r}) \exp(i2\pi \mathbf{k} \cdot \mathbf{r}) \, d\mathbf{r} \quad [2]$$

where $\exp(i2\pi \mathbf{k} \cdot \mathbf{r})$ is the local spin phase factor for the spins at position $\mathbf{r}$, $\mathbf{k} = (2\pi)^{-1} \gamma \mathbf{G} t$, and $\rho(\mathbf{r})$ is the density of spins at position $\mathbf{r}$ and is the quantity we seek to image. The remarkable fact about eqn [2] is that it is a simple Fourier transform in which $\mathbf{k}$ is the reciprocal-space wave vector conjugate to the spatial dimension $\mathbf{r}$. Thus the acquisition of a signal in a domain of ‘ $\mathbf{k}$ -space’ leads to direct computation of $\rho(\mathbf{r})$ by means of Fourier inversion, a fact that is made possible by the ability of the NMR experiment to provide full phase information (i.e. the complex number $S(\mathbf{k})$ via the acquisition of both in-phase (real) and quadrature-phase (imaginary) signals).

Figure 1 Radiofrequency probe, gradient coils set and RF coil inserts used in NMR microscopy. The probe assembly is placed in the 89 mm diameter vertical bore of a superconducting magnet. The set of RF coils and resonators enable samples of different sizes to be inserted, and have diameters ranging from 25 mm diameters down to 2 mm. Generally one acquires an image of the spin distribution in a 2-dimensional planar 'slice', with a frequency-selective RF pulse being used to excite only spins within a pre-selected plane, and the k -space encoding being applied independently for two orthogonal directions within the plane, one direction via a fixed time duration variable-magnitude gradient pulse (phase-encoding) and the other direction via a fixed gradient pulse with the signal being sampled at successive time points during the evolution (read-encoding). A typical pulse sequence that performs these tasks along with the corresponding k -space map is shown in **Figure 2**. Note that this sequence employs the spin-echo method in which a separate 180° RF pulse is used to invert spin phases. This allows us to traverse both negative and positive regions of k -space. The spin echo has important applications in the measurement of transverse relaxation, and of molecular flow and diffusion.

Note also that the finite time needed to encode the NMR magnetization in k -space requires that the nuclear spin relaxation time, T_2 , be sufficiently long. T_2 is determined predominantly by internuclear interactions, which in turn are motionally averaged by molecular tumbling. This means in effect that molecules in the liquid state have long proton T_2 values (10–1000 μ s) while those in the solid state may have relaxation times as short as 10 μ s. This results in a sharp discrimination of the signal in which the solid state component is entirely filtered out, unless special rapid-encoding methods are used. Most NMR microscopy images therefore arise from the liquid phase alone. Readers interested in the rarer solid-state options should consult references given under Further Reading.

Limits to Resolution

The fundamental spatial resolution for NMR microscopy is limited by the three factors of intrinsic signal-to-noise, molecular self-diffusion and diamagnetic susceptibility effects. For protons at room temperature and with an RF coil at room temperature, the signal-to-noise limit is easily calculated under optimal experimental conditions and depends directly on the ratio of T_1 to T_2 , the available experimental time for signal averaging, and the magnetic field strength. Typical resolution limits for superconducting magnet systems for imaging times of the order of 30 min are $(10\ \mu\text{m})^3$ and $(20\ \mu\text{m})^3$ for T_1/T_2 values of unity and 100, respectively. These estimates assume 256×256 pixels with the sample exactly filling a solenoidal RF coil, a consequence of which is that the RF coil dimensions must progressively decrease with increasing resolution, thus limiting the highest resolution to very small samples. Note that resolution in one dimension can be traded against another so that it is possible to observe finer details (in-plane resolution) if a thicker slice can be tolerated. One of the highest-resolution examples yet reported, at $(4.5\ \mu\text{m})^2$ in-plane and 70 μm slice thickness, was obtained using a sample of onion cells contained with an RF coil of 1 mm diameter (see **Figure 3**).

In principle, the resolution could be further improved if the receiver coil temperature and/or its electrical resistance could be lowered. Some progress has been reported on the use of liquid nitrogen-cooled superconducting ceramics in which an effective signal-to-noise

Figure 2 RF and magnetic field gradient pulse sequence used in NMR microscopy along with the associated trajectory through k -space. The frequency-selective 180° pulse is used to select a layer of spins (the slice plane) to participate in the spin echo and hence to contribute to the image. NT = acquisition time; T_E = echo time.

increase was obtained. The need for inductive coupling and the problem of poor filling factor means in effect that no major advantage has resulted to date.

The fact that the NMR imaging signal arises from nuclei whose parent molecules exist in a liquid state implies that imaging resolution will be strictly limited by self-diffusion. A rule of thumb is that diffusion limits will be important when the rms Brownian displacements over the k -space encoding time are comparable with the pixel dimension. The usual consequence is severe signal attenuation, an effect that is apparent in **Figure 4**, which shows an image from water contained in a rectangular capillary of $100\text{ }\mu\text{m}$ wall spacing. Here only the layer of molecules near the wall, whose motions are impeded by the boundary, fails to suffer attenuation and therefore presents a bright edge effect. Such phenomena can provide potentially useful contrast. Another effect that also has its origin in boundaries associated with structural heterogeneity is illustrated in **Figure 5** which shows high-resolution NMR-microscope images of a section of

geranium stem at two different read gradient strengths for which the acquisition times, NT , and echo time T_E (see **Figure 2**) are different by a factor of 5. The image obtained at longer acquisition and echo time (**Figure 5a**) suffers from attenuation and distortion effects due to the differing diamagnetic susceptibility across cell wall boundaries. Note that the pixel dimension is $10\text{ }\mu\text{m}$ while the slice thickness is $500\text{ }\mu\text{m}$. The subtle interplay between diffusion and susceptibility effects can also result in characteristic bright image features seen in **Figure 5a**. It is apparent that the susceptibility and diffusion effects can provide image features that are useful in discriminating boundaries between fluid regions. These complex phenomena and their elucidation are discussed in more detail in references listed at the end of the article.

Image Contrast

The particular utility of NMR microscopy lies in the contrasts that are available. These include, in addition to

Figure 3 NMR image (a) and corresponding optical micrograph (b) of the epidermal cells of *Allium cepa*. The pixel size is $5\text{ }\mu\text{m}$ with a slice thickness of $70\text{ }\mu\text{m}$. the usual spin density (or, by implication, molecular density), the susceptibility effects discussed above, the chemical shift (the small changes in frequency due to different electronic environments of the nuclei), the nuclear spin relaxation times (sensitive to the rotational dynamics of parent molecules and hence ideally suited to discriminating solids, liquids and semisolid phases), the molecular translational self-diffusion coefficient and the molecular translational flow rate. Each contrast, if it is to be appropriately quantified or enhanced, requires a particular modification to the basic imaging pulse sequence shown in **Figure 2**, details of which can be found in the

book by Callaghan. For example, in the case of chemical shift imaging, the initial 90° RF pulse can be made frequency-selective so as to excite only those spins residing in a particular chemical site. For relaxation contrast the echo time can be altered by adjusting delay times or pulse repetition times. However, because the imaging pulse sequence is based on the use of magnetic field gradients in conjunction with spin echoes, this can make the image intensity especially sensitive to the effects of molecular self-diffusion when one is close to the diffusion limit. This is the reason for the bright edge effects seen in **Figure 4**.

Figure 4 NMR micrograph obtained from water in a rectangular glass capillary whose walls are spaced by $100\ \mu\text{m}$. The pixel dimension is $8\ \mu\text{m}$, comparable with the distance diffused by the water molecules over the echo time T_E , and hence the image intensity is severely attenuated, except at the walls where the molecular Brownian motion is restricted. A commonly used approach is to leave the parameters of the imaging spatial encoding (the part to the right of the grey line in **Figure 2**) unchanged and to add the pulse sequence needed for contrast encoding as a precursor. For example, in the case of T_2 contrast this would take the form of a prior $90_x - \tau - 180_y - \tau$ spin-echo segment where the remaining echo amplitude used for

spatial encoding depends on the relaxation that occurs over the delay time τ . By acquiring separate images at different delay times τ , one generates a three-dimensional data set (two for the image within the slice plane and one additional for τ). Analysis in the third dimension enables one to display an image of relaxation rate. Another higher-dimensional encoding is that needed for

molecular self-diffusion or flow analysis. This method is so important to NMR microscopy that it requires a separate discussion.

Pulsed Gradient Spin-Echo NMR

Encoding for Translational Motion

The spin echo allows one to perform a useful trick in the encoding of spin positions. Consider the pulse sequence shown in **Figure 6**. At the echo maximum (the point where $k=0$), the phase excursions of the spins return to zero, unless, that is, any of the parent molecules happen to have moved along the direction of the gradient. In this case the subtraction performed by the echo is imperfect and the residual phase shifts provide a signature for motion.

The pulsed gradient spin echo (PGSE) experiment of **Figure 6** uses two narrow gradient pulses of amplitude g , duration δ and separation Δ . These pulses effectively define the starting and finishing point of spin translational motion over the well-defined timescale, Δ . A spin that moves by a distance R over time Δ will acquire a phase shift, $\gamma\delta g \cdot R$. Indeed the resulting phase encoding can be expressed in the same reciprocal space language that we have already seen; the difference now is that the wave vector, q ($q=(2\pi)^{-1}\gamma\delta g$), is conjugate to molecular displacements over the time Δ between the gradient pulses, rather than in the case of imaging where it is conjugate to the actual spin positions. The analogue to eqn [2] is given by the echo amplitude

$$E(q, \Delta) = \int \overline{P}_s(R, \Delta) \exp[i2\pi q \cdot R] dR \quad [3]$$

where the ‘average propagator’, $\overline{P}_s(R, \Delta)$, gives the probability that a spin in the ensemble examined displaces by R over the encoding time Δ . Just as inverse Fourier transformation of $S(k)$ in eqn [2] returns an image of the spin density $\rho(r)$, so inverse Fourier transformation of $E(q, \Delta)$ with respect to q returns an image of the average propagator, $\overline{P}_s$.

Diffusion and Flow

In the case of two simple examples of motion of importance in NMR microscopy, namely self-diffusion and flow, the propagator takes the form

$$\overline{P}_s(R, \Delta) = (4\pi D_s \Delta)^{-3/2} \exp\left(-\frac{(R - v\Delta)^2}{4D_s \Delta}\right) \quad [4]$$

where v is the constant velocity and D_s is the self-diffusion coefficient. When the PGSE encoding is used

as a higher contrast dimension in conjunction with NMR imaging, the signal acquired is effectively modulated in both k -space and q -space. Generally the experiment is performed with two dimensions of k (the slice planes) and one dimension of q (where $q=|q|$) so that the signal is

$$\int S(k, q) = \int \rho(r) E(q, \Delta) \exp(i2\pi k \cdot r) dr \quad [5]$$

Inverse Fourier transformation of $S(k, q)$ with respect to k returns a set of 2-dimensional images modulated by $E(q, \Delta)$ while transformation with respect to q returns, for every image pixel, $\overline{P}_s(Z, \Delta)$, the average propagator for displacements Z along the gradient axis at position r within the image. By appropriate processing of these average propagators, details of the local motion can be calculated. For example, the width of $\overline{P}_s(Z, \Delta)$ is determined by the rms Brownian motion $(2D_s \Delta)^{1/2}$ while the displacement of $\overline{P}_s(Z, \Delta)$ along the Z axis is determined by the flow displacement $v\Delta$, where v is the local molecular velocity. In this manner maps of $D_s(r)$ and $v(r)$ may be constructed, examples of which are shown in **Figure 6b**.

Applications of NMR Microscopy

Numerous factors militate against the widespread use of NMR microscopy: the resolution is poor by optical standards, the apparatus is expensive, the technique requires a high level of scientific expertise and the arrangements for sample loading are inconvenient and restrictive. Set against these are the uniquely noninvasive character of the method, its sensitivity to fluid phases, its unique ability to measure specific molecular properties and the especially powerful insights it can provide regarding fluid dynamics. Studies in which NMR microscopy has been able to provide unrivalled information include those concerned with membrane filtration, flow and dispersion in porous media, non-Newtonian flow in viscoelastic fluids, nonequilibrium phase transitions, electrophoresis and electroosmosis, interdiffusion of fluids, and the monitoring of chemical wave propagation. In biology the method has provided new insights into plant physiology *in vivo*, multicellular tumour development and angiogenesis in tumours, while the method enables detailed MRI investigations concerning rat and mouse physiology in the study of diseases and their treatment. It should be noted that while the majority of applications of the method have concerned ^1H NMR, there are a number of important examples of its applications using other nuclei, including ^{19}F , ^{31}P , ^{13}C , ^2H and ^{17}O . These rarer nuclei allow site- or molecular-specific

labelling and provide the opportunity to investigate new contrast schemes, for example the mapping of pH in the case of ^{31}P .

A few examples selected from this range of applications are mentioned here. First, the use of NMR microscopy as a chemical mapping tool in plant physiology is illustrated in **Figure 7**, where two images of a castor bean stem cross section are illustrated alongside the total NMR spectrum from the stem. The spectral regions in the initial excitation pulse are indicated by the vertical line in each case and the images correspond to (a) water and (b) fructose. The sugar image is intense precisely at the phloem regions within the vascular bundles. There are many interesting applications of relaxation time weighting in order to obtain useful image contrast, some of which can be seen in chapter 5 of the book by Callaghan. One example from that chapter concerns profiles taken across several growth rings of a wood segment in which the water components associated with early wood, late wood and cell walls are separated by different spin relaxation times. This illustrates the potential of NMR microscopy to resolve differing aqueous components in porous media, in biological tissue and in food products. Another example concerns the sensitivity of T_1 and T_2 to the oxidation state of ions, an effect that is put to use in the imaging of chemical waves associated with the Belusov–Zhabotinsky reaction.

Figures 8 and 9 show applications of NMR microscopy in the rheological investigation of complex viscoelastic fluids. In **Figure 8** comparative velocity and diffusion profiles are shown across the diameter of a 700 μm diameter capillary through which is pumped a solution of high-molecular-mass polymer undergoing laminar flow. The velocity profile is distinctly non-Poiseuille, consistent with shear thinning, while the polymer self-diffusion coefficients exhibit a dramatic enhancement once the shear rate (the velocity gradient) exceeds a characteristic value. This value corresponds to the slowest relaxation rate of the molecule τ_d^{-1} , where τ_d is the so-called tube disengagement time. τ_d indicates the time taken for the polymer to completely reconfigure its conformation. This diffusion enhancement phenomenon is associated with the breakdown of chain entanglements under shear and illustrates the changes that occur when an externally imposed rate of strain competes with the natural Brownian dynamics of a molecular system. In the example shown here, the crossover in the competition can be observed because the diameter of the capillary is sufficiently small that high shear rates can be observed, thus emphasizing the importance of the microscopic length scale.

The second example, shown in **Figure 9**, also illustrates some of the strange phenomena apparent when competitive crossover occurs in systems that exhibit flow instability or are close to a phase transition. The image

shows the velocity profile obtained for a wormlike micelle solution sheared in the gap of a cone-and-plate rheometer, along with the resultant shear rate of the fluid. Flow instability phenomena have led to distinctive shear

banding, in effect a first-order phase transition of the fluid maintained under non-equilibrium conditions. Microscopy has been able to provide unique insight in this emerging area of condensed-matter physics.

Figure 9 Stacked profile map (a) of the fluid velocity across the gap of a 7° cone and plate system containing a semidilute wormlike micelle solution, and shear rate image (b) obtained by taking the derivative of the velocity across the gap. Dramatic shear banding effects are apparent. Note the use of an expanded field of view across the gap achieved by using different magnitudes of spatial encoding gradients. Courtesy of MM Britton and the author.

Diffraction Phenomena and Higher Spatial Resolution

The diffractive physics at the heart of NMR imaging means in effect that any degree of structural homogeneity can be used to advantage in improving resolution. For example, in a periodic structure, the raw signal $S(k)$ will contain coherence peaks whose spacing bears an inverse relationship to the separations of 'scattering centres' in real space. Shorter-range spatial correlations can be investigated using Patterson function ($|S(k)|^2$) analysis. An entirely different but related diffraction phenomenon arises in the PGSE NMR experiment from the diffusion or dispersion of fluid within pores, where the boundary restrictions to molecular translation result in distinctive coherences in $E(q)$. All these approaches have the potential to greatly extend the resolution by which NMR

field gradient methods can be used to probe liquid-phase morphology in materials science and biology.

Conclusion

NMR microscopy is an expensive and sophisticated technique that requires specialist insight in order to gain maximum advantage. Every new application requires a significant degree of spectroscopic optimization (e.g. RF and gradient pulse sequence design) and hardware optimization (e.g. RF antenna and sample holding design) if the best results are to be achieved. The method has now been realistically assessed and is likely to find extensive use in chemical physics and in chemical engineering in the study of fluid dynamics, multiphase flow and dispersion, restricted diffusion and flow in porous media, the rheology of soft condensed matter, phase separation and chemical instability, pH and temperature mapping, permeation and interdiffusion, and in research concerning electrophoresis and current imaging. In biological applications the method has unrivalled capability in studying the distribution and transport of specific molecular species in plant and insect physiology *in vivo*. In medical research it is proving an important tool in rat and mouse studies *in vivo* and it holds considerable promise as a complementary method in histology.

While the intrinsic insensitivity of NMR confines both the spatial and the temporal resolution possible in NMR microscopy, a number of important new technical developments may yet extend those limits. These include the use of superconducting RF coils, and the use of indirect optical pumping techniques to greatly enhance nuclear polarization. Furthermore, in systems exhibiting a degree of structural homogeneity, the limits to resolution may be significantly enhanced by taking advantage of diffraction methodology. These latter approaches, while scientifically challenging, provide a nice link between the field of NMR spectroscopy and the wealth of scattering techniques that are so widely used in the study of condensed matter.

Symbols

B_0	magnetic flux density
D	dipolar interaction tensor
$\mathcal{H}$	interaction Hamiltonian
p	order of multiquantum coherence
P_i	rotation about the i -axis
R	dipolar coupling constant
T_1, T_2	relaxation times
γ	nuclear gyromagnetic ratio
η	asymmetry parameter
ν_Q	quadrupole frequency
ν_L	Larmor resonance frequency
σ_{zz}	shielding constant
τ	time interval between pulses

Introduction

NMR spectra cannot normally be measured in solids in the same way in which they are routinely obtained from liquids. For example, the width of the ^1H NMR line in the spectrum of water is ~ 1 Hz, while the line from a static sample of ice is ~ 100 kHz wide. The reason for this is the existence of net anisotropic interactions which in the liquid are exactly averaged by the rapid thermal tumbling of molecules. A typical high-resolution spectrum of an organic compound in solution contains a wealth of information. The frequency of the radiation absorbed by the various non-equivalent nuclei in the molecule depends subtly on their chemical environments, giving rise to very sharp spectral lines. The parameters derived from such a spectrum (positions, widths, intensities and multiplicities of lines, relaxation mechanisms and rates) provide detailed information on the structure, conformation and molecular motion. This is not the case in a solid, where the nuclei are static and a conventional NMR spectrum is a broad hump which conceals most structural information. Although certain solids have sufficient molecular motion for NMR spectra to be obtainable without resorting to special techniques, we are concerned here with the general case, where there is no motion of nuclei and where conventional NMR, instead of sharp spectral lines, yields a broad hump which conceals information of interest to a chemist. Although the study of moments of such spectra and of various

temperature-dependent parameters can still yield information on the degree of crystallinity, interatomic distances and molecular motion ('wide-line NMR'), we shall be primarily interested in ways of achieving high-resolution spectra, i.e. spectra which enable magnetically non-equivalent nuclei of the same spin species (e.g. ^{13}C) to be resolved as individual lines.

The interactions to be considered in the solid state and their Hamiltonians are as follows:

- (1) Zeeman interaction with the magnetic field, $\mathcal{H}_Z$;
- (2) chemical shielding, $\mathcal{H}_{CS}$;
- (3) dipolar interaction, $\mathcal{H}_D$;
- (4) J -coupling, $\mathcal{H}_J$;
- (5) quadrupolar interaction, $\mathcal{H}_Q$.

The total Hamiltonian is a sum of all these contributions:

$$\mathcal{H} = \mathcal{H}_Z + \mathcal{H}_{CS} + \mathcal{H}_D + \mathcal{H}_J + \mathcal{H}_Q \quad [1]$$

with the quadrupolar term $\mathcal{H}_Q$ non-zero only for nuclei with $I > \frac{1}{2}$. In general, $\mathcal{H}_Z$, $\mathcal{H}_{CS}$, $\mathcal{H}_D$ and $\mathcal{H}_Q$ are much larger than $\mathcal{H}_J$. J -Coupling is rarely observed in solids so that $\mathcal{H}_J$ will henceforward be neglected.

The interaction Hamiltonians have the general form

$$\mathcal{H} = \mathbf{I} \cdot \mathbf{A} \cdot \mathbf{S} = \begin{bmatrix} I_x & I_y & I_z \end{bmatrix} \begin{bmatrix} A_{xx} & A_{xy} & A_{xz} \\ A_{yx} & A_{yy} & A_{yz} \\ A_{zx} & A_{zy} & A_{zz} \end{bmatrix} \begin{bmatrix} S_x \\ S_y \\ S_z \end{bmatrix} \quad [2]$$

where $\mathbf{I}$ and $\mathbf{S}$ are vectors and $\mathbf{A}$ is a second-rank Cartesian tensor. We shall consider the various interactions in turn.

The Zeeman Interaction

The Zeeman Hamiltonian, which determines the resonance frequency of an NMR-active nucleus in the magnetic field $\mathbf{B}_0$, is

$$\mathcal{H}_Z = \mathbf{I} \cdot \mathbf{Z} \cdot \mathbf{B}_0 \quad [3]$$

where $\mathbf{Z} = -\gamma \hbar \mathbf{1}$, $\mathbf{I} = [I_x, I_y, I_z]$, $\mathbf{B}_0 = [B_x, B_y, B_z]$ and $\mathbf{1}$ is a unit matrix. When the magnetic field is aligned with the z -axis of the laboratory frame of reference, $\mathbf{B}_0 = [0, 0, B_0]$. The Zeeman interaction, which is directly proportional

to the strength of the magnetic field, is thus entirely under the operator's control.

Magnetic Shielding

The effect known as the chemical shift, central to the application of NMR in chemistry, is caused by simultaneous interactions of a nucleus with surrounding electrons and of the electrons with the static magnetic field $\mathbf{B}_0$. The field induces a secondary local magnetic field which opposes $\mathbf{B}_0$, thereby 'shielding' the nucleus from its full effect. The shielding Hamiltonian is

$$\mathcal{H}_{\text{CS}} = -\gamma \hbar \mathbf{I} \cdot \boldsymbol{\sigma} \cdot \mathbf{B}_0 \quad [4]$$

The shielding is anisotropic, which is quantified in terms of a second-rank tensor $\boldsymbol{\sigma}$ ('the chemical shielding tensor'):

$$\boldsymbol{\sigma} = \begin{bmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} \end{bmatrix} \quad [5]$$

In strong magnetic fields $\boldsymbol{\sigma}$ is axially symmetric. When transformed into its principal reference system (PAS) by using rotation matrices, the tensor is described by three principal components σ_{ii} ($i = 1, 2, 3$):

$$\begin{bmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} \end{bmatrix} \xrightarrow{\text{Rotation}} \begin{bmatrix} \sigma_{11} & 0 & 0 \\ 0 & \sigma_{22} & 0 \\ 0 & 0 & \sigma_{33} \end{bmatrix}$$

and three direction cosines, $\cos\theta_i$, between the axes of PAS and the laboratory frame.

The observed shielding constant, σ_{zz} , is a linear combination of the principal components:

$$\sigma_{zz} = \sum_{i=1}^3 \sigma_{ii} \cos^2\theta_i = \frac{1}{3} \text{Tr } \boldsymbol{\sigma} + \frac{1}{3} \sum_{i=1}^3 (3\cos^2\theta_i - 1) \sigma_{ii} \quad [6]$$

where $\text{Tr } \boldsymbol{\sigma}$ stands for the trace of the tensor. Since the average value of each $\cos^2\theta_i$ is $\frac{1}{3}$, the average value of σ_{zz} in the NMR spectra of liquids (where there is random molecular tumbling) is the isotropic value:

$$\overline{\sigma_{zz}} = \frac{1}{3} \text{Tr } \boldsymbol{\sigma} = \sigma_{\text{iso}} \quad [7]$$

In solids the angle-dependent second term on the right of eqn [6] survives, giving rise to a spread of resonance frequencies, i.e. line broadening.

Dipolar Interactions

The Hamiltonian for the dipolar interaction between a pair of nuclei i and j separated by the internuclear vector $\mathbf{r}$ is given by

$$\mathcal{H}_{\text{D}} = R \mathbf{I}_i \cdot \mathbf{D} \cdot \mathbf{I}_j = R \begin{bmatrix} I_{ix} & I_{iy} & I_{iz} \end{bmatrix} \times \begin{bmatrix} r^2 - 3x^2 & -3xy & -3xz \\ -3xy & r^2 - 3y^2 & -3yz \\ -3xz & -3yz & r^2 - 3z^2 \end{bmatrix} \begin{bmatrix} I_{jx} \\ I_{jy} \\ I_{jz} \end{bmatrix} \quad [8]$$

where $R = \gamma_i \gamma_j \hbar \mu_0 / 4\pi r^3$ is the dipolar coupling constant, γ the nuclear gyromagnetic ratio and $\mathbf{D}$ the dipolar interaction tensor. In the PAS of the tensor, with the internuclear vector aligned along one of the coordinate axes, we have $xy = yz = zx = 0$, $r^2 = x^2 + y^2 + z^2$ and the tensor becomes

$$\mathbf{D} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad [9]$$

It is clearly traceless ($\text{Tr } \mathbf{D} = 1 - 2 + 1 = 0$).

The truncated dipolar interaction Hamiltonian may be written in the form

$$\mathcal{H}_{\text{D}} = \frac{\gamma_i \gamma_j \hbar^2}{2r^3} [\mathbf{I}_i \cdot \mathbf{I}_j - 3I_{iz} I_{jz}] (3\cos^2\theta - 1) \quad [10]$$

where θ is the angle between $\mathbf{r}$ and the external magnetic field $\mathbf{B}_0$. Since the average value $\overline{\cos^2\theta_{ij}} = \frac{1}{3}$, the isotropic average of the Hamiltonian is $\overline{\mathcal{H}_{\text{D}}} = 0$ so that the dipolar interaction does not affect the NMR spectrum in solution. In the solid the interaction remains, greatly increasing the spectral line width.

Quadrupolar Interactions

Some 74% of all NMR-active nuclei have $I > \frac{1}{2}$ so that, in addition to magnetic moment, they possess an electric quadrupole moment brought about by non-spherical distribution of the nuclear charge. The quadrupole interaction broadens and shifts the NMR lines, and also affects their relative intensities.

When the quadrupolar Hamiltonian is considered as a perturbation on the Zeeman Hamiltonian, there is no general analytical solution for the eigenvalues of $\mathcal{H}_{\text{Z}}$ in the (very rare) case when $\mathcal{H}_{\text{Z}}$ and $\mathcal{H}_{\text{Q}}$ are of comparable magnitude. When $\mathcal{H}_{\text{Q}} \gg \mathcal{H}_{\text{Z}}$, the splitting of the nuclear states is very large and 'pure quadrupole resonance' (NQR) is observed even in the absence of a magnetic

field. In the usual 'high field' case, $\mathcal{H}_Z \gg H_Q$, the quadrupole Hamiltonian in the PAS of the electric field gradient tensor is

$$\mathcal{H}_Q = \frac{e^2 q Q}{4I(2I-1)} \left[3I_z^2 - I^2 + \eta (I_x^2 - I_y^2) \right] \quad [11]$$

where η is the asymmetry parameter which describes the symmetry of the electric field gradient. The definitions of η and of the 'quadrupole frequency', ν_Q , which describes the magnitude of the interaction, are

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} \quad \nu_Q = \frac{3e^2 q Q}{2I(2I-1)\hbar} \quad [12]$$

Perturbation theory allows us to calculate the energy levels $E^{(0)}_m$, $E^{(1)}_m$ and $E^{(2)}_m$ (superscripts denote the order). Because of the first- and second-order shifts in energy levels, instead of a single (Larmor) resonance frequency $\nu_L = [E^{(0)}_{m-1} - E^{(0)}_m]$, as with spin- $\frac{1}{2}$ nuclei, there are now several resonance frequencies:

$$\nu_m = \frac{E_{m-1} - E_m}{\hbar} = \nu_L + \nu_m^{(1)} + \nu_m^{(2)} \quad [13]$$

Detailed calculations reveal that:

- (1) The first-order frequency shift is zero for $m = \frac{1}{2}$ so that the central transition for non-integer spins (such as ^{27}Al with $I = \frac{5}{2}$) is not affected by quadrupolar interactions to first order. It is thus advantageous to work with such nuclei, especially since the central transition is normally the only one which is observed: other transitions are so broadened and shifted as to be unobservable.
- (2) The first-order shift is scaled by $\frac{1}{2}(3 \cos^2 \theta - 1)$.
- (3) The second-order shift increases with ν_Q^2 and is inversely proportional to the magnetic field strength. Since the dispersion of the chemical shift, which is what we normally wish to measure, is proportional to B_0 , it is advantageous to work at high fields, where the chemical shift effects make the maximum contribution to the spectrum. As the second-order frequency shift is always present for all transitions, the feasibility of obtaining useful spectra depends on the magnitude of ν_Q .

The very small quadrupole interactions of ^2H and their sensitivity to molecular motion at a wide range of frequencies make this integer spin nucleus very useful for chemical studies. ^2H NMR experiments normally use static samples, and dynamic information is extracted by comparing spectra measured at different temperatures with model computer simulations.

Magic-Angle Spinning

Magic-angle spinning (MAS) is by far the most powerful tool in solid-state NMR. The technique averages anisotropic interactions by acting on the factor $(3 \cos^2 \theta - 1)$ in the Hamiltonians, which in solids is not averaged to zero by rapid molecular motion. MAS was first introduced to deal with the dipolar interaction. It can be shown that when the sample is rapidly spun around an axis inclined at the angle β to the direction of the magnetic field, the time-averaged value of the angle θ , which an arbitrary internuclear vector makes with B_0 , is

$$\overline{3 \cos^2 \theta - 1} = \frac{1}{2} (3 \cos^2 \beta - 1) (3 \cos^2 \chi - 1) \quad [14]$$

where χ , the angle between the internuclear vector and axis of rotation, is constant for each vector, because the solid is rigid. The result is that the term $\frac{1}{2}(3 \cos^2 \beta - 1)$ scales the spectral width, and that for $\beta = \cos^{-1}(1/\sqrt{3}) = 54.74^\circ$ (the 'magic angle'), $3 \cos^2 \theta - 1 = 0$. The dipolar Hamiltonian in eqn [10] is averaged to zero.

For MAS to be effective, the sample must be spun at a rate greater than the static spectral width expressed in Hz. As the homonuclear ^1H - ^1H interactions may lead to spectra which are as much as 50 kHz wide, it is not possible to spin the sample fast enough. Thus high-resolution solid-state ^1H spectra of most organic compounds, where protons are generally close together, cannot be obtained with the use of MAS alone, but require the additional use of multiple-pulse techniques (see below). However, MAS is successful in removing homonuclear interactions for ^{13}C , ^{31}P and nuclei of small gyromagnetic ratios.

The chemical shift anisotropy is also reduced by MAS, because the tensor interactions controlling all anisotropic interactions in solids all have a common structure and may be expressed in terms of Wigner rotation matrices which are scaled by MAS.

High-Power Decoupling

When dilute spins, such as ^{13}C , interact via the dipolar interaction with ^1H or other abundant nuclei, the large heteronuclear broadening of an already low-intensity spectrum is a considerable problem. High-power decoupling, used to remove heteronuclear coupling effects, applies a continuous, very highpower pulse at the ^1H resonance frequency in a direction perpendicular to B_0 . The ^{13}C pulse is then applied, and the ^{13}C free induction decay measured while continuing the ^1H irradiation. The powerful decoupling pulse stimulates rapid ^1H spin transitions, so rapid that the ^{13}C spins experience only the time-average of the ^1H magnetic moment, i.e. zero.

Since the technique relies on selective excitation of the abundant and dilute nuclei, it can only remove hetero-nuclear interactions.

Cross-Polarization

Dilute nuclei, such as ^{13}C and ^{15}N , are more difficult to observe than abundant nuclei, such as ^1H or ^{31}P , particularly when they also have a low gyromagnetic ratio. However, the dilute and abundant nuclei are often in close proximity, and coupled via the dipolar interaction. Cross-polarization (CP) exploits this interaction to observe dilute nuclei, at the same time overcoming two serious problems often encountered in solid-state NMR: (i) because of a very small population difference in the polarized sample, NMR actually observes very few dilute spins and consequently the sensitivity of the experiment is low; (ii) spin-lattice relaxation times of spin- $\frac{1}{2}$ nuclei in solids are often very long so that long delays are required between experiments and the spectral signal-to-noise ratio is poor.

The sequence of events during the ^{13}C - ^1H CP experiment is as follows. After the end of the 'preparation period', during which the sample polarizes in the magnetic field, a $\pi/2$ pulse is selectively applied to ^1H along the x -axis of the rotating frame, aligning the ^1H magnetization with the y -axis. A long pulse of amplitude $B_{1\text{H}}$ is then applied along the y -axis. Since the ^1H magnetization is now aligned with the effective field in the rotating frame, it becomes 'spin locked' along this direction. At the same time, a long pulse of amplitude $B_{1\text{C}}$ is selectively applied to ^{13}C along the x -axis. The amplitudes $B_{1\text{H}}$ and $B_{1\text{C}}$ are adjusted so as to satisfy the Hartmann-Hahn condition:

$$\gamma_{\text{H}} B_{1\text{H}} = \gamma_{\text{C}} B_{1\text{C}} \quad [15]$$

The energies of ^1H and ^{13}C in the rotating frame are thus equal, and the two spin reservoirs can transfer magnetization in an energy-conserving manner during the 'contact time'. Finally, the ^{13}C radiofrequency field is turned off and a free induction decay observed in the usual way. During the observation time the ^1H field is still on, but serves as the high-power decoupling field to reduce the ^1H - ^{13}C dipolar broadening.

Detailed arguments show that the magnetization of ^{13}C nuclei is theoretically increased by the factor of $\gamma_{\text{H}}/\gamma_{\text{C}} \approx 4$. After the ^{13}C free induction decay signal has been measured, the magnetization of carbons is again almost zero, but the loss of proton magnetization is small. The CP experiment can be repeated without waiting for the carbons to relax. The only limitations are the gradual loss of polarization by the ^1H spin reservoir, and the decay of the ^1H magnetization during spin locking. The latter process proceeds on a time-scale ('spin-lattice

relaxation in the rotating frame') which is much shorter than the ^{13}C spin-lattice relaxation time.

Multiple-Pulse Line Narrowing

Although homonuclear dipolar couplings are in principle removable by MAS, with abundant nuclei they are often very strong. For example, the removal of the ^1H - ^1H interaction in most organic compounds requires spinning rates far in excess of what is practically feasible. The alternative to MAS is to manipulate the nuclear spins themselves using 'multiple-pulse line narrowing' so as to average the dipolar interaction. The method uses specially designed sequences of pulses with carefully adjusted phase, duration and spacing. The result is that, when the signal is sampled at a certain moment during the sequence, the dipolar interaction is averaged to zero.

WAHUHA, the simplest multiple pulse sequence, is composed of four 90° pulses:

$$(P_x - 2\tau - P_x - \tau - P_y - 2\tau - P_y - \tau)n \text{ times} \quad [16]$$

where P_i represents rotation about the particular i -axis of the rotating frame and τ is the time interval between pulses. Over the sequence, the magnetic moments spend equal amounts of time along each of the three principal axes. The NMR signal is sampled in one of the 2τ windows. Sequences have been developed involving from 4 to as many as 52 pulses. The entire sequence must be short relative to the relaxation time T_2 , and the pulses themselves must also be very short.

Multiple pulse sequences not only average the dipolar Hamiltonian but also affect other Hamiltonians to an extent which depends on the particular sequence. For example, the WAHUHA sequence scales chemical shift anisotropies by a factor of $1/\sqrt{3}$.

Moments of an NMR Line

Even when the dipolar ^1H - ^1H interaction is not removed from the spectrum, the method of moments can provide important structural information. The n th moment of the line shape $f(\omega)$ about ω_0 is defined as

$$M_n = \frac{\int_0^\infty (\omega - \omega_0)^n f(\omega) d\omega}{\int_0^\infty f(\omega) d\omega} \quad [17]$$

where

$$M_0 = \int_0^\infty f(\omega) d\omega$$

is the area under the line (the zeroth moment). For a normalized function, $M_0 = 1$. The second moment is

physically analogous to the moment of inertia of an object with the same shape as the line. If $f(\omega)$ is an even function of ω , $M_n=0$ for all odd values of n . It is convenient to calculate moments about the centre of gravity of the line shape, i.e. the value of ω_0 for which the first moment is zero.

The second moment can be calculated from the interatomic distances in the solid containing pairs i, j of dipolar-coupled nuclei. Van Vleck has shown that, for a polycrystalline powder composed of randomly oriented crystals in which we observe identical spin- $\frac{1}{2}$ nuclei, the second moment is

$$M_2^{\text{homo}} = \frac{9}{16} \gamma^4 \hbar^2 \left(\frac{\mu_0}{4\pi} \right)^2 \sum_j \frac{1}{r_{ij}^6} \quad [18]$$

while for pairs of unlike nuclei the second moment is different:

$$M_2^{\text{hetero}} = \frac{1}{4} \gamma_i^2 \gamma_j^2 \hbar^2 \left(\frac{\mu_0}{4\pi} \right)^2 \sum_j \frac{1}{r_{ij}^6} \quad [19]$$

Thus, even when the interacting nuclei have very similar gyromagnetic ratios, the homonuclear second moment is larger by a factor of $\frac{9}{4}$ than the heteronuclear moment. This is because dipolar coupling between unlike spins cannot lead to an energy conserving mutual spin flip. The second moment is thus very sensitive to the kind of neighbour.

The method of moments has further advantages. First, since the second moment is inversely proportional to the sixth power of the internuclear distance, it is a very sensitive means of determining interatomic distances. Second, it can provide insights into the structure. For example, it was used to demonstrate the presence of groups of three equivalent protons in solid hydrates of strong acids, thus proving the presence of hydronium ions, H_3O^+ . Third, it is useful for the study of motion, because the moments are dramatically reduced when the dipolar interaction is partly or completely averaged out by an onset of a specific motion.

DOR, DAS and MQ-MAS

We have seen that the second-order quadrupolar interaction, which affects all quadrupolar nuclei, is reduced, but not removed, by MAS. Its complete removal is clearly of importance in solid-state NMR. Three different techniques have been proposed to achieve this aim.

When the second-order quadrupole interaction is expanded as a function of Wigner rotation matrices, and we consider the case of a sample rapidly rotated about an angle β with respect to B_0 , the average second-order

quadrupolar shift of the central transition becomes

$$v_{\frac{1}{2}}^{(2)} = \frac{v_Q^{(2)}}{v_L} \left[I(I+1) - \frac{3}{4} \right] [A_0 + B_2 P_2(\cos \beta) + B_4 P_4(\cos \beta)] \quad [20]$$

where v_Q is the quadrupole frequency, v_L is the Larmor frequency, A_0 and B_0 are constants and the $P_n(\cos \beta)$ terms are the Legendre polynomials

$$P_2(\cos \beta) = \frac{1}{2}(3 \cos^2 \beta - 1)$$

$$P_4(\cos \beta) = \frac{1}{8}(35 \cos^4 \beta - 30 \cos^2 \beta + 3) \quad [21]$$

There is no value of β for which both the $P_2(\cos \beta)$ and the $P_4(\cos \beta)$ terms can be zero so that the angle-dependent terms cannot be averaged by spinning about a single axis. Instead, in the ingenious 'double-rotation' (DOR) experiment the sample is spun *simultaneously* about two different axes β_1 and β_2 so that

$$P_2(\cos \beta_1) = 0 \quad P_4(\cos \beta_2) = 0 \quad [22]$$

with solutions $\beta_1 = 54.74^\circ$ (the conventional magic angle) and $\beta_2 = 30.56$ or 70.12° . As a result, only the A_0 term remains in eqn [20]. This is accomplished by a rotor-within-a-rotor probehead in which the centres of gravity of the two rotors, each spinning at a different angle with respect to B_0 , exactly coincide. Although the daunting engineering problems posed by the design of a DOR probehead have been overcome, it is very difficult to spin the two rotors simultaneously at sufficiently high spinning speeds, and the spinning rates are limited to ~ 6 and 1 kHz for the inner and outer rotors, respectively, compared with ~ 30 kHz achievable with MAS. This is an unfortunate limitation, since multiple spinning sidebands appear in the spectra if the rate of the rotation is lower than the strength of the quadrupolar interaction.

The technique known as 'dynamic-angle spinning' (DAS) adopts an alternative approach to DOR: the sample is rotated *sequentially* about two different axes, β_1' and β_2' , which are chosen so that

$$\begin{aligned} P_2(\cos \beta_1') &= -P_2(\cos \beta_2') \\ P_4(\cos \beta_1') &= -P_4(\cos \beta_2') \end{aligned} \quad [23]$$

with the solutions $\beta_1' = 37.38^\circ$ and $\beta_2' = 79.19^\circ$. The rotation axis is switched very rapidly, which poses technical problems, given that the minimum time required for changing the spinning angle must be shorter than the relaxation time of the nucleus being observed. As a result, DAS often cannot be applied to many nuclei, including ^{27}Al , and is limited to the study of nuclei with long relaxation times (for example in amorphous samples, such as glasses).

Yet another solution to the problem, known as 'multiple-quantum magic-angle spinning' (MQ-MAS), relies on the fact that B_2 and B_4 are functions of I, p, η, α and β , where p is the order of the multiquantum coherence and α and β are the Euler angles corresponding to the orientation of each crystallite in the powder with respect to the rotor axis. Under fast MAS, the chemical shift anisotropy, heteronuclear dipolar interactions and the term proportional to P_2 in eqn [20] are removed so that

$$v_{\frac{1}{2}}^{(2)} = \frac{v_Q^{(2)}}{v_L} \left[I(I+1) - \frac{3}{4} \right] [A_0 + B_4 P_4(\cos 54.74^\circ)] \quad [24]$$

Although the second term, proportional to P_4 , still causes substantial line broadening, it can be eliminated by using

p -quantum transitions. A p -quantum transition (with $p=3$ or 5 for ^{27}Al) is excited and the signal allowed to evolve during time t_1 . As multiple quantum transitions are not directly observable by NMR, a second pulse converts the signal into a single-quantum transition, which is observable. The technique enables a two-dimensional representation of the spectra, with a regular increment of t_1 providing a ' p -quantum dimension', free of quadrupolar interactions. Although the optimal conditions for MQ-MAS are difficult to establish, the technique is being increasingly used for the study of quadrupolar nuclei of half-integer spin, such as ^{27}Al , ^{85}Rb , ^{23}Na , ^{11}B and ^{93}Nb .

Note that DOR, DAS and MQ-MAS do not remove the A_0 term in eqns [20] and [24]. Thus the position of

the line in the spectrum, however narrow, does not correspond to the pure chemical shift, but includes the effect of the quadrupole interaction.

Modern Solid-State NMR

Magic-angle spinning has greatly enhanced our knowledge of a wide range of materials used in chemical, physical, biological and earth sciences and in the technology of glass and ceramics. It took nearly twenty years, since its discovery in 1958, for MAS to become a routine tool of structural investigation. The reasons were the difficulty of spinning the sample at the very high speeds required and the insufficiently high magnetic fields. However, the introduction of Fourier-transform NMR, cross-polarization and superconducting magnets during the 1960s and 1970s greatly improved the sensitivity of the spectra and enabled virtually all NMR-active nuclei to be observed in solids. ^1H MAS NMR was used to examine polymers as early as 1972, and Schaefer and Stejskal were the first to combine CP and MAS in ^{13}C NMR studies of organics. Much important work, at first mostly with ^{13}C but later with other nuclei, has been done since. Since the early 1980s great progress has been made in the study of ^{29}Si and ^{27}Al in natural and synthetic molecular sieve catalysts and minerals, which is particularly significant since nearly a half of all known minerals are silicates or aluminosilicates.

High-resolution spectra of solids are now routinely obtained using a combination of CP and MAS (see **Figure 1**), and it is fair to say that CP-MAS has revolutionized materials science. The otherwise weak signals from dilute nuclei (such as ^{13}C or ^{29}Si) are enhanced by cross-polarization, heteronuclear dipolar interactions are

removed by high-power decoupling, chemical shift anisotropy and the weak dipolar interactions between dilute nuclei are averaged by fast MAS, and the signal-to-noise ratio is increased further, thanks to the more frequent repetition of the experiment and the availability of high magnetic fields. Although the line widths in such high-resolution spectra are still greater than those measured in liquids, the various non-equivalent nuclei can in most cases be separately resolved.

Symbols

$\mathbf{B}$	magnetic field vector
B	magnitude of $\mathbf{B}$
$\hbar$	Planck constant (h)/ 2π
$\mathbf{I}$	nuclear spin angular momentum vector
I	nuclear spin quantum number
J	spin–spin coupling constant
m	nuclear magnetic quantum number
$\mathbf{M}$	classical (macroscopic) magnetization vector
T_1	spin–lattice relaxation time
T_2	spin–spin relaxation time
γ	gyromagnetic ratio
μ	nuclear magnetic moment
μ_z	z component
δ	chemical shift
σ	shielding (screening) constant
τ_c	rotational correlation time
ω	angular frequency
ω_0	Larmor frequency

Nuclear magnetic resonance spectroscopy is an extraordinarily powerful source of information on the structure and dynamics of molecules. Almost every molecule one can think of has at least one magnetic nucleus already in place, exceedingly sensitive to its surroundings but interacting very weakly with them. As such, nuclear spins are ideal probes of molecular properties at the atomic level.

NMR spectra of molecules in liquids contain essentially five sources of information: the intensities of individual resonances (which depend on the number of nuclei responsible), chemical shifts (the interaction of nuclear spins with an applied magnetic field), spin–spin coupling (their interactions with one another), spin relaxation (the restoration of thermal equilibrium), and chemical exchange (the effects of conformational and chemical equilibria).

Spin Angular Momentum and Nuclear Magnetism

Most atomic nuclei have an intrinsic angular momentum known as *spin*. Like the angular momentum of a

gyroscope, nuclear spin is a vector quantity – it has both magnitude and direction. Unlike classical angular momentum, however, nuclear spin is quantized. Its magnitude is

$$\sqrt{I(I+1)}\hbar \quad [1]$$

where I is the *spin quantum number* of the nuclide in question and $\hbar$ is Planck's constant h divided by 2π . I may be zero, or a positive integer or half-integer:

$$I = 0, \frac{1}{2}, 1, \frac{3}{2}, 2, \dots \quad [2]$$

Table 1 gives the spin quantum numbers of some popular NMR nuclei.

The projection of the angular momentum vector $\mathbf{I}$ onto an arbitrary axis (labelled z) is also quantized:

$$I_z = m\hbar \quad [3]$$

where the *magnetic quantum number*, m , can have values between $+I$ and $-I$ in integral steps:

$$m = +I, +I-1, \dots, -I+1, -I \quad [4]$$

The spin of a nucleus with $I = \frac{1}{2}$ (e.g. ^1H) has magnitude $(\sqrt{3}/2)\hbar$ and z component $I_z = \pm \frac{1}{2}\hbar$; for $I = 1$ (e.g. ^2H), the spin angular momentum is $\sqrt{2}\hbar$, and $I_z = 0$ or $\pm\hbar$ (**Figures 1a** and **1b**). According to the uncertainty principle, the other two (x and y) components of the angular momentum cannot be known once the magnitude and the z component of $\mathbf{I}$ have been specified.

Closely associated with nuclear spin is a *magnetic moment* μ

$$\mu = \gamma \mathbf{I} \quad [5]$$

which is parallel or sometimes antiparallel to $\mathbf{I}$, with a proportionality constant γ called the *gyromagnetic ratio*. As

a consequence, both the magnitude and orientation of μ are quantized. In the absence of a magnetic field, all $2I+1$ states of a spin- I nucleus are degenerate, and the direction of the quantization axis is arbitrary.

In an applied magnetic field B_0 with strength B_0 , the spins are quantized along the field direction (the z -axis) and have an energy

$$E = -\mu \cdot B_0 = -\mu_z B_0 \quad [6]$$

where $\mu \cdot B_0$ is the scalar product of the two vectors, and μ_z is the projection of μ onto B_0 . Since $\mu_z = \gamma I_z$ and $I_z = m\hbar$, it follows that

$$E = -m\hbar\gamma B_0 \quad [7]$$

That is, the $2I+1$ states are split apart in energy, with a uniform gap $\Delta E = \hbar\gamma B_0$ between adjacent levels (Figures 1c and 1d).

The NMR experiment involves applying electromagnetic radiation of the correct frequency ν to ‘flip’ spins from one energy level to another, according to the selection rule $\Delta m = \pm 1$, i.e.

$$h\nu = \Delta E = \hbar\gamma B_0 \quad [8]$$

which may be rearranged to give the *resonance condition*

$$\nu = \frac{\gamma B_0}{2\pi} \quad [9]$$

The NMR frequency of a nucleus is proportional to its γ and to the strength of the field; the $2I$ allowed transitions of a spin- I nucleus have identical frequencies (e.g. Figure 1d). Typical magnetic fields used in modern

Table 2 Gyromagnetic ratios, NMR frequencies (in a 9.4 T field), and natural isotopic abundances of selected nuclides

	γ ($10^7 \text{ T}^{-1} \text{ s}^{-1}$)	ν (MHz)	Natural abundance (%)
^1H	26.75	400.0	99.985
^2H	4.11	61.4	0.015

^{31}P	10.84	162.1	100.0

NMR spectroscopy are in the range 4.7–22.3 T, giving proton (^1H) resonance frequencies of 200–950 MHz, falling in the *radiofrequency* region of the electromagnetic spectrum. Table 2 gives the gyromagnetic ratios, resonance frequencies in a 9.4 T field, and natural isotopic abundances of some commonly studied NMR nuclei.

The intensity of the observed NMR signal depends on the difference between the numbers of nuclei in the states involved in the transition. At thermal equilibrium the fractional difference in populations, of a spin- $\frac{1}{2}$ nucleus with positive γ , is given by the Boltzmann distribution:

$$\frac{n_\alpha - n_\beta}{n_\alpha + n_\beta} = \frac{e^\Delta - e^{-\Delta}}{e^\Delta + e^{-\Delta}} \approx \Delta = \frac{\hbar\gamma B_0}{2kT} = \frac{h\nu}{2kT} \quad [10]$$

where α and β denote the $m = +\frac{1}{2}$ and $m = -\frac{1}{2}$ levels, k is the Boltzmann constant, and T is the temperature in kelvin. The approximation made in eqn [10] is that the NMR energy gap $\hbar\gamma B_0$ is tiny by comparison with kT , which is the situation in essentially all NMR experiments. For protons (^1H) in a 9.4 T field, $\nu = 400$ MHz so that $\Delta = 3.2 \times 10^{-5}$, giving a population difference of about one part in 31 000.

Chemical Shifts

Although the resonance frequency of a nucleus in a magnetic field is determined principally by γ , it also depends, slightly, on the immediate surroundings of the nucleus. This effect, the *chemical shift*, is of crucial importance for chemical applications of NMR because it allows one to distinguish nuclei in different environments. For example, the ^1H spectrum of liquid ethanol (Figure 2) shows clearly that there are three types of protons (methyl, methylene and hydroxyl).

The chemical shift exists because the applied magnetic field B_0 causes electrons in atoms and molecules to circulate around the nuclei. Somewhat like an electric current in a loop of wire, the swirling electrons generate a small local magnetic field that augments or opposes B_0 .

Figure 2 Schematic ^1H NMR spectrum of liquid ethanol, $\text{C}_2\text{H}_5\text{OH}$. The three multiplets, at chemical shifts of 1.2, 3.6 and 5.1 ppm arise from the CH_3 , CH_2 , and OH protons. The multiplet structure (quartet for the CH_2 , triplet for the CH_3) arises from the spin–spin coupling of the two sets of protons. Splittings are not normally seen from the coupling of the OH and CH_2 protons, because the hydroxyl proton undergoes rapid intermolecular exchange, catalysed by traces of acid or base.

This induced field B_{ind} is proportional in strength to B_0 and, in atoms, is antiparallel to it. The net field B experienced by the nucleus is thus slightly different from B_0 :

$$B = B_0 - B_{\text{ind}} = B_0 - \sigma B_0 = B_0(1 - \sigma) \quad [11]$$

where the proportionality constant σ is known as the *shielding* or *screening constant*. The resonance condition, eqn [9], thus becomes

$$\nu = \frac{\gamma B}{2\pi} = \frac{\gamma B_0}{2\pi}(1 - \sigma) \quad [12]$$

The shielding constant is determined by the electronic structure of the molecule in the vicinity of the nucleus: ν is thus a characteristic of the chemical environment.

The relation between the energy levels of a pair of spin- $\frac{1}{2}$ nuclei A and X,

$$\frac{E}{h} = -\frac{m_A \gamma B_0 (1 - \sigma_A)}{2\pi} - \frac{m_X \gamma B_0 (1 - \sigma_X)}{2\pi} = -m_A \nu_A - m_X \nu_X \quad [13]$$

and the NMR spectrum is shown in **Figure 3**.

The chemical shift is customarily quantified by means of a parameter δ , defined in terms of the resonance frequencies of the nucleus of interest and of a reference compound:

$$\delta = 10^6 \times \left(\frac{\nu - \nu_{\text{ref}}}{\nu_{\text{ref}}} \right) \quad [14]$$

δ is dimensionless and independent of B_0 ; values are usually quoted in parts per million (ppm). The most commonly used reference compound for ^1H and ^{13}C NMR is tetramethylsilane, $(\text{CH}_3)_4\text{Si}$.

NMR spectra are displayed with δ increasing from right to left, with the reference compound at $\delta = 0$. As a consequence, nuclei with higher resonance frequencies (i.e. those that are less shielded) appear towards the left-hand side of the spectrum. Although spectra are now normally recorded at a fixed field strength, the old terms ‘upfield’ and ‘downfield’, meaning ‘more shielded’ and

Figure 3 Energy levels and NMR spectrum of a pair of spin- $\frac{1}{2}$ nuclei, A and X. m_A and m_X are the magnetic quantum numbers, ν_A and ν_X are the two resonance frequencies, and E is the energy. The spin–spin coupling J_{AX} is zero.

‘less shielded’, dating from the days of field-swept NMR, are still in common use.

Chemical shifts are easily converted into frequency differences using eqn [14]. For example, the chemical shifts of the methyl and methylene signals of ethanol (**Figure 2**) are 1.2 and 3.6 ppm, respectively, giving a difference in resonance frequencies in a 9.4 T field of $(3.6 - 1.2) \times 10^{-6} \times 400 \text{ MHz} = 960 \text{ Hz}$.

The relative intensities of the signals in an NMR spectrum are proportional to the population differences (eqn [10]), and therefore to the numbers of nuclei responsible for each signal. The CH_3 , CH_2 , and OH resonances of ethanol (**Figure 2**), for example, thus have integrated areas in the ratio 3:2:1.

Spin–Spin Coupling

Magnetic nuclei interact not only with applied and induced magnetic fields but also with one another. The result, for molecules in liquids, is a fine structure known as *spin–spin coupling*, *scalar coupling* or *J-coupling*, illustrated by the ^1H spectrum of ethanol in **Figure 2**.

The effect of spin–spin coupling on a pair of nuclear spins A and X is to shift their energy levels by amounts determined by the two magnetic quantum numbers and by the parameter that quantifies the strength of the interaction, the *spin–spin coupling constant*, J_{AX} . Thus, eqn [13] becomes

$$\frac{E}{h} = -m_A \nu_A - m_X \nu_X + J_{AX} m_A m_X \quad [15]$$

For spin- $\frac{1}{2}$ nuclei, the energies are raised or lowered by $\frac{1}{4}J_{AX}$ according to whether the spins are parallel ($m_A m_X = +\frac{1}{4}$) or antiparallel ($m_A m_X = -\frac{1}{4}$). Equation [15] leads to the modified resonance condition for spin A:

$$\nu = \nu_A - J_{AX} m_X \quad [16]$$

i.e. the resonance frequency of A is shifted from its chemical shift position by an amount that depends on the orientation of the X spin to which it is coupled. Since X has in general $2I+1$ states, the A resonance is split into $2I+1$ uniformly spaced lines, with equal intensities (because the different orientations of X are almost exactly equally likely). The effect that spin-spin coupling has on the energy levels of two spin- $\frac{1}{2}$ nuclei is shown in **Figure 4**. Each nucleus now has two NMR lines (a doublet).

The origin of spin-spin coupling is not the direct, through-space *dipolar interaction* of two magnetic moments: being purely anisotropic, this interaction is averaged to zero by the rapid end-over-end tumbling of molecules in liquids. Rather, the nuclei interact via the electrons in the chemical bonds that connect them. The interaction usually falls off rapidly as the number of intervening bonds increases beyond 3 so that the existence of a scalar coupling between two nuclei normally indicates that they are close neighbours in a molecular framework.

Equation [16] can easily be extended to describe more than two nuclei:

$$\nu = \nu_A - \sum_{i \neq A} J_{Ai} m_i \quad [17]$$

Figure 4 Energy levels and NMR spectrum of a pair of spin- $\frac{1}{2}$ nuclei, A and X. m_A and m_X are the magnetic quantum numbers, ν_A and ν_X are the two resonance frequencies, J_{AX} is the spin-spin coupling constant, and E is the energy.

where the sum runs over all spins to which A has an appreciable coupling. If A is coupled to N identical spin- $\frac{1}{2}$ nuclei (e.g. the three protons in a methyl group), it can be seen from eqn [17] that its resonance is split into $N+1$ equally spaced lines with relative intensities given by the binomial coefficients

$$\binom{N}{i} = \frac{N!}{i!(N-i)!}, \quad i = 0, 1, 2, \dots, N \quad [18]$$

Thus, the CH_2 and CH_3 resonances in ethanol (**Figure 2**) are respectively a 1:3:3:1 quartet and a 1:2:1 triplet.

This discussion of the *multiplet* (i.e. doublet, triplet, quartet, ...) structure arising from spin-spin coupling is valid in the *weak coupling* limit, i.e. when the difference in resonance frequencies of the coupled nuclei $|\nu_A - \nu_X|$ is much larger than their interaction $|J_{AX}|$. When this is not the case (*strong coupling*), the positions and intensities of the lines are modified, as illustrated in **Figure 5**. The origin of these effects lies in the NMR transition probabilities. As the coupling becomes stronger, the outer line of each doublet in **Figure 5** becomes weaker relative to the inner line. In the limit that the chemical shift difference is zero, the transitions leading to the two outer lines become completely forbidden, and the two inner lines coincide so that only a single line is observed. This is a general result: *spin-spin interactions between protons in identical environments do not lead to observable splittings*.

Vector Model of NMR

Considerable insight into the operation of simple NMR experiments may be derived from a straightforward *vector model*. It relies on the fact that while the individual nuclear magnetic moments behave quantum mechanically, the net magnetization of a large collection of nuclear spins obeys classical mechanics.

The motion of a classical magnetic moment $\mathbf{M}$, possessing angular momentum, in a magnetic field $\mathbf{B}$ is described by the differential equation

$$\frac{d\mathbf{B}}{dt} = -\gamma \mathbf{B} \times \mathbf{M} \quad [19]$$

Figure 5 Calculated NMR spectra of a pair of spin- $\frac{1}{2}$ nuclei for a range of $\delta\nu = \nu_A - \nu_X$ values between $16J_{AX}$ and zero.

or equivalently,

$$\begin{aligned}\frac{dM_{x'}}{dt} &= -\gamma B_{y'} M_{z'} + \gamma B_{z'} M_{y'} \\ \frac{dM_{y'}}{dt} &= +\gamma B_{x'} M_{z'} - \gamma B_{z'} M_{x'} \\ \frac{dM_{z'}}{dt} &= -\gamma B_{x'} M_{y'} + \gamma B_{y'} M_{x'}\end{aligned}\quad [20]$$

where $\mathbf{B} \times \mathbf{M}$ is the vector product of $\mathbf{B} = (B_{x'}, B_{y'}, B_{z'})$ and $\mathbf{M} = (M_{x'}, M_{y'}, M_{z'})$, and the (x', y', z') coordinate system is called the *laboratory frame*.

These expressions describe the precession of $\mathbf{M}$ around $\mathbf{B}$ at *angular* frequency $\omega = \gamma B$, as may be seen by taking $\mathbf{B} = \mathbf{B}_0$, along the z' axis:

$$\begin{aligned}\frac{dM_{x'}}{dt} &= +\gamma B_0 M_{y'} \\ \frac{dM_{y'}}{dt} &= -\gamma B_0 M_{x'} \\ \frac{dM_{z'}}{dt} &= 0\end{aligned}\quad [21]$$

(see **Figure 6**). This motion is known as *Larmor precession*, and it occurs at the NMR frequency of the nuclear spins in the field $\mathbf{B}_0$:

$$\omega_0 = \gamma B_0 = 2\pi\nu \quad [22]$$

An NMR experiment involves the application of a brief, intense burst of radiofrequency radiation, known as a 'pulse', along, say, the x' axis in the laboratory frame. The frequency of this field, ω_{RF} , is very close to the Larmor frequency ω_0 . Regarding this linearly oscillating field as the sum of two counter-rotating fields, we may ignore the component that rotates in the opposite sense to the Larmor precession because, being $2\omega_{\text{RF}}$ off-resonance, it has a negligible effect on the spins. The other component is

$$\mathbf{B}_1 = (B_1 \cos \omega_{\text{RF}} t, -B_1 \sin \omega_{\text{RF}} t, 0) \quad [23]$$

The nuclear spins thus experience the sum of two magnetic fields: a strong static field $\mathbf{B}_0$ along the z' axis, and a much weaker, time-dependent field $\mathbf{B}_1$ rotating in the $x'y'$ plane. $\mathbf{M}$ therefore precesses around the time-dependent vector sum of $\mathbf{B}_0$ and $\mathbf{B}_1$ (**Figure 7a**). To make this complicated motion easier to visualize, eqn [20] is transformed into the *rotating frame* (x, y, z) , a coordinate system rotating around the z' axis at frequency ω_{RF} in which the radiofrequency field appears stationary. In this frame, the components of the bulk magnetization are

$$\begin{aligned}M_x &= M_{x'} \cos \omega_{\text{RF}} t - M_{y'} \sin \omega_{\text{RF}} t \\ M_y &= M_{x'} \sin \omega_{\text{RF}} t + M_{y'} \cos \omega_{\text{RF}} t \\ M_z &= M_{z'}\end{aligned}\quad [24]$$

Figure 6 The motion of a magnetization vector $\mathbf{M}$ in a magnetic field $\mathbf{B}_0$. $\mathbf{M}$ precesses around the field direction rather like the axis of a spinning gyroscope.

Figure 7 The magnetic fields present in an NMR experiment in (a) the laboratory frame and (b) the rotating frame. $\mathbf{B}_0$ is the strong static field, $\mathbf{B}_1$ is the much weaker oscillating radiofrequency field, $\Delta\mathbf{B}$ and $\mathbf{B}_{\text{eff}}$ are respectively, the offset and effective fields in the rotating frame, and $\mathbf{B}(t)$ is the resultant of $\mathbf{B}_0$ and $\mathbf{B}_1$ in the laboratory frame.

Differentiating eqns [24] and using eqns [20] with $\mathbf{B} = (B_1 \cos \omega_{\text{RF}} t, -B_1 \sin \omega_{\text{RF}} t, B_0)$ give

$$\begin{aligned}\frac{dM_x}{dt} &= +\gamma \Delta B M_y \\ \frac{dM_y}{dt} &= +\gamma B_1 M_z - \gamma \Delta B M_x \\ \frac{dM_z}{dt} &= -\gamma B_1 M_y\end{aligned}\quad [25]$$

or, more compactly,

$$\frac{d\mathbf{M}}{dt} = -\gamma \mathbf{B}_{\text{eff}} \times \mathbf{M} \quad [26]$$

where $\mathbf{B}_{\text{eff}} = (B_1, 0, \Delta B)$, and $\Delta B = B_0 - \omega_{\text{RF}}/\gamma$. Equation [26] describes the precession of $\mathbf{M}$ about a static field $\mathbf{B}_{\text{eff}}$

at frequency $\gamma B_{\text{eff}} = \gamma \sqrt{B_1^2 + \Delta B^2}$ in the rotating frame (Figure 7b). $\gamma \Delta B = \omega_0 - \omega_{\text{RF}} = \Omega$ is the offset of the radiofrequency field from resonance. To include chemical shifts, γB_0 should be replaced by $\gamma B_0(1 - \sigma)$.

Radiofrequency Pulses

At equilibrium, in the absence of a radiofrequency field, the bulk magnetization of the sample M_0 is parallel to the B_0 direction (z axis) with a magnitude proportional to the population difference ($n_\alpha - n_\beta$, for a spin- $\frac{1}{2}$ nucleus). If the radiofrequency field strength is much larger than the resonance offset ($B_1 \gg \Delta B$) then $B_{\text{eff}} \cong B_1$ and the effective field lies along the x axis in the rotating frame. The pulse therefore causes M_0 to rotate in the yz plane at frequency γB_1 (Figure 8a and 8b). In this way a short, intense monochromatic burst of radiofrequency radiation can excite spins uniformly over a range of resonance frequencies, provided their offset frequencies Ω are much smaller than γB_1 . If the field is switched off after a time t_p , given by $\gamma B_1 t_p = \pi/2$, M is turned through 90° and is left along the y axis (Figure 8c). A radiofrequency pulse with this property is known as a 90° pulse. If t_p is twice this duration, the magnetization is *inverted* (a 180° pulse, Figure 8d); this is equivalent to exchanging the n_α and n_β populations of a spin- $\frac{1}{2}$ nucleus.

Free Precession

Equation [26] may also be used to predict what happens *after* a 90° pulse. Setting $B_1 = 0$, the effective field is $B_{\text{eff}} = (0, 0, \Delta B)$ and M precesses in the xy plane at angular frequency $\gamma \Delta B = \Omega$, i.e. at the offset frequency determined by ω_{RF} and the chemical shift (Figure 8e):

$$\begin{aligned} M_x &= M_0 \sin \Omega t \\ M_y &= M_0 \cos \Omega t \\ M_z &= 0 \end{aligned} \quad [27]$$

where t is now the time after the end of the pulse. When several nuclei with different chemical shifts have been excited by the pulse, the xy magnetization of the sample is the sum of several oscillating terms of the form of eqn [27].

Free Induction Decay

Up to this point it has been assumed that the non-equilibrium state produced by the radiofrequency pulse does not relax back towards equilibrium. This is a reasonable approximation during the very short pulse. However, to describe the behaviour of the spins during the period of free precession that follows the pulse,

Figure 8 The effect of radiofrequency pulses (in the rotating frame). (a) At thermal equilibrium, the net magnetization of the sample is parallel to the B_0 direction. (b) A pulse along the x axis, whose strength B_1 is much greater than the offset field ΔB , causes M to rotate in the yz plane at angular frequency γB_1 . (c) A 90° pulse, of duration t_p ($\gamma B_1 t_p = \pi/2$), rotates the magnetization from the 'north pole' (z axis) to the 'equator' (y axis). (d) A 180° pulse, of duration t_p ($\gamma B_1 t_p = \pi$), rotates the magnetization from the 'north pole' to the 'south pole' ($-z$ axis). (e) Following a 90° pulse, the magnetization precesses around the 'equator' in the rotating frame at frequency $\Omega = \gamma \Delta B$. Relaxation is ignored throughout.

relaxation must be included. This is traditionally done by allowing M_x and M_y to decay exponentially back to zero with a time constant T_2 , while M_z grows back to M_0 with a time constant T_1 :

$$\begin{aligned}\frac{dM_x}{dt} &= +\gamma\Delta B M_y - \frac{M_x}{T_2} \\ \frac{dM_y}{dt} &= +\gamma B_1 M_z - \gamma\Delta B M_x - \frac{M_y}{T_2} \\ \frac{dM_z}{dt} &= -\gamma B_1 M_y - \frac{(M_z - M_0)}{T_1}\end{aligned}\quad [28]$$

T_1 and T_2 are the *spin-lattice* and the *spin-spin relaxation times*. These expressions are known as the *Bloch equations*. With relaxation included, eqn [27] becomes

$$\begin{aligned}M_x(t) &= M_0 \sin \Omega t \exp(-t/T_2) \\ M_y(t) &= M_0 \cos \Omega t \exp(-t/T_2) \\ M_z(t) &= M_0 [1 - \exp(-t/T_1)]\end{aligned}\quad [29]$$

The two components M_x and M_y represent the detectable signal in an NMR experiment – the *free induction decay* (Figure 9). Fourier transformation of the free induction decay gives the NMR spectrum.

Spin Relaxation

Relaxation processes allow nuclear spins to return to equilibrium following a disturbance, e.g. a radiofrequency pulse. The relaxation times T_1 and T_2 characterize the relaxation of, respectively, the *longitudinal* and *transverse* components of the magnetization $\mathbf{M}$, respectively parallel and perpendicular to $\mathbf{B}_0$. Equivalently, T_1 is the time constant for the return to equilibrium of the populations of the spin states, while T_2 is the time constant for the dephasing of the *coherence* between spin states. In the absence of any significant spatial inhomogeneity of $\mathbf{B}_0$, or other sources of line broadening such as chemical exchange, the width of the NMR line (in hertz) is $1/\pi T_2$.

Spin-lattice relaxation is caused by randomly fluctuating local magnetic fields. A common source of such fields is the dipolar interaction between pairs of nuclei, modulated by molecular tumbling in a liquid. The component of these fields that oscillates at the resonance frequency can induce transitions between the spin states, so transferring energy between the spin system and the 'lattice' (i.e. everything else) and bringing the spins into equilibrium with their surroundings. In the simplest case, T_1 depends on the mean square strength of the local fields $\langle B_{\text{loc}}^2 \rangle$, and the intensity of the fluctuations at the resonance frequency ω_0

$$\frac{1}{T_1} = \gamma^2 \langle B_{\text{loc}}^2 \rangle J(\omega_0) \quad [30]$$

Figure 9 Following a 90° pulse, the magnetization precesses around the z axis and at the same time returns to its equilibrium position at the 'north pole' (a). The transverse components of $\mathbf{M}$ decay to zero with time constant T_2 , the spin-spin relaxation time (b). The z component of $\mathbf{M}$ grows back to M_0 with time constant T_1 , the spin-lattice relaxation time (c).

where

$$J(\omega) = \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad [31]$$

is the *spectral density* function, and τ_c is the *rotational correlation time* (roughly the average time the molecule takes to rotate through 90°).

Spin-spin relaxation has two contributions:

$$\frac{1}{T_2} = \frac{1}{2}\gamma^2 \langle B_{\text{loc}}^2 \rangle J(\omega_0) + \frac{1}{2}\gamma^2 \langle B_{\text{loc}}^2 \rangle J(0) \quad [32]$$

The first is closely related to spin-lattice relaxation, and arises from the finite lifetime of the spin states, through the uncertainty principle. The second term is due to the loss of coherence caused by local fields of very low frequency (hence the $J(0)$ factor), which augment or oppose $\mathbf{B}_0$ and so give rise to a spread of resonance frequencies,

Figure 10 The dependence of T_1 and T_2 on the rotational correlation time τ_c , using $\gamma^2 \langle B_{loc}^2 \rangle = 4.5 \times 10^9 \text{ s}^{-2}$ and $\omega_0/2\pi = 400 \text{ MHz}$. The units for the vertical axis are seconds.

and hence the dephasing of transverse magnetization. **Figure 10** shows the dependence of T_1 and T_2 on τ_c .

Relaxation times contain information on both $J(\omega)$ (i.e. on molecular motion) and $\langle B_{loc}^2 \rangle$ (i.e. on molecular structure via, for example, the r^{-3} distance dependence of the dipolar interaction). A further relaxation phenomenon that provides important information on inter-nuclear distances is the *nuclear Overhauser effect*.

Chemical Exchange

In addition to chemical shifts, spin–spin coupling and spin relaxation, NMR spectra are affected by, and may be used to study, chemical and conformational equilibria. Consider an equilibrium

which exchanges the chemical shifts of two nuclei, with equal forward and backward rate constants, k . At low temperature, the NMR spectrum comprises two sharp resonances at frequencies ν_A and ν_B . As the temperature is raised, the following sequence of events occurs: the two lines broaden and move towards one another until they coalesce into a broad flat-topped line which then narrows into a sharp single resonance at the average chemical shift $\frac{1}{2}(\nu_A + \nu_B)$ (**Figure 11**).

The mid-point of this process, when the two lines just merge into one, occurs when

$$k = \frac{\pi(\nu_A - \nu_B)}{\sqrt{2}} = \frac{\pi\delta\nu}{\sqrt{2}} \quad [34]$$

Figure 11 Calculated NMR spectra for a pair of nuclei exchanging between two sites with equal populations. Spectra are shown for a range of values of the exchange rate k . The difference in resonance frequencies of the two sites, $\delta\nu$, is 50 Hz.

For *slow exchange*, the exchange broadening of the two separate resonances is

$$\Delta\nu = \frac{k}{\pi} \quad [35]$$

while for *fast exchange*, the single line has an extra width

$$\Delta\nu = \frac{\frac{1}{2}\pi(\delta\nu)^2}{k} \quad [36]$$

Related but more complex expressions are found if the forward and backward rate constants differ, or if there are more than two exchanging species.

Symbols

B_0	external magnetic field vector
B_1	rotating magnetic field vector arising from RF electromagnetic radiation
u	dispersion mode
M	resultant of individual magnetic moment vectors
v	absorption mode
α, β	spin states corresponding to allowed values of m_l
α	angle of rotation of M with respect to initial axis
γ	magnetogyric ratio for nucleus, i.e. the ratio of magnetic moment/spin angular momentum
Δ	fixed delay
θ	phase of coherence
ν	frequency (s^{-1})
$\Delta\nu$	frequency difference
ϕ	phase of pulse or receiver
ω	angular velocity (rad s^{-1})

Introduction

The single most important development in nuclear magnetic resonance (NMR) spectroscopy since the initial observation of the NMR phenomenon in bulk phases in 1945 was undoubtedly the introduction of pulse Fourier transform NMR by Anderson and Ernst. This technique provided greatly increased sensitivity per unit time, making it feasible to obtain spectra for low sensitivity/low abundance nuclei such as ^{13}C . More importantly, it allowed the development of a wide variety of sophisticated and powerful multipulse experiments which have revolutionized the use of NMR spectroscopy in studies of molecular structure and dynamics. This article provides an overview of pulse sequence experiments. Many individual experiments are discussed in other articles.

The Classical Vector Model of NMR and the Basic One-Pulse Fourier Transform Experiment

Many NMR pulse sequences can be described either by a classical model describing the motions of magnetic

vectors or by quantum mechanical models of different levels of sophistication. The attractive feature of the classical vector model is that it provides simple physical pictures of many of the basic pulse sequences. However, it does not work for many multipulse experiments that involve multiple quantum coherence. These experiments can only be described by quantum mechanical methods. Because of the insights which the vector model provides into many of the basic sequences, I will use this model wherever possible.

The fundamental magnetic properties of nuclei are well described elsewhere. I will begin with the bulk magnetization vector M for a series of nuclei of the same type. This is parallel to the external magnetic field B_0 and is the resultant of individual magnetic moment vectors μ , precessing about B_0 with the Larmor angular velocity

$$\omega = -\gamma B_0 \quad [1]$$

where γ is the magnetogyric ratio of the nucleus (Figure 1). For a nucleus with spin quantum number $I = \frac{1}{2}$, M actually results from the slight excess of nuclei in the α spin state ($m_l = +\frac{1}{2}$) over those in the β spin state ($m_l = -\frac{1}{2}$).

Now consider the effect of a 'pulse' of electromagnetic radiation of frequency corresponding to the Larmor frequency $\omega/2\pi$. This is applied so that the oscillating magnetic component of the pulse is in a plane at right angles to B_0 . This oscillating component can be resolved into two rotating components of angular velocity $\pm 2\pi\nu$. Only the component rotating in the same direction as the magnetic moments need to be considered since the opposite component has no net effect on the nuclear magnetization. The former component is represented by a magnetization vector, B_1 , rotating in the x - y plane at frequency ν . However, to simplify the visualization, the Cartesian coordinate system is also assumed to be rotating at frequency ν , called the rotating frame model (Figure 2). This allows us to concentrate on frequency differences rather than absolute frequencies in considering NMR experiments.

During the pulse, the individual magnetic moments and consequently the bulk magnetization vector precess about B_1 with angular velocity γB_1 . If B_1 is taken as defining the x -axis in the rotating frame, M rotates towards the y -axis through an angle:

$$\alpha(\text{radians}) = \gamma B_1 \tau \quad [2]$$

Figure 1 (a) The precession of an individual magnetic moment μ about the external magnetic field B_0 . (b) The precession of magnetic moments in the α ($m_I = +\frac{1}{2}$) and β ($m_I = -\frac{1}{2}$) spin states. (c) The resultant magnetic moment M of a large number of nuclei of the same kind, reflecting the small excess population of nuclei in the α spin state.

Figure 2 The rotating frame coordinate system. The coordinate system is assumed to be rotating at the same frequency as B_1 and consequently B_1 appears to be stationary along the x-axis. The x,y magnetization M , generated after a pulse, will be stationary along the y-axis if the Larmor precession frequency is equal to the pulse frequency or rotating at a frequency $\Delta\nu$, corresponding to the frequency difference.

where τ is the pulse duration in seconds. Thus if the duration of the pulse is just sufficient to rotate M through $\pi/2$ radians, it is called a 90° pulse. The resultant magnetization generated in the x - y plane can then be detected by a receiver.

Now consider the one-pulse Fourier transform experiment. The pulse sequence is illustrated in **Figure 3**. The pulse does not excite a single frequency but rather a range of frequencies whose width (in Hz) is inversely proportional to the pulse duration (in s). The frequency excitation profile is provided by taking the Fourier transform of the time profile of the pulse (**Figure 3**). Quadrature detection distinguishes positive and negative frequencies, allowing one to position the transmitter frequency at the midpoint of the spectral window.

Figure 3 (a) The basic pulse Fourier transform sequence; τ represents the pulse duration and Δ is a small delay, comparable to τ , to ensure that the pulse is not detected by the receiver. Note that in this and subsequent pulse sequences, the duration of the pulse is exaggerated. The actual pulse duration is $\sim 10\mu\text{s}$ compared with an acquisition time, t_1 , of $\sim 1\text{ s}$. (b) (i) The time profile of the pulse and (ii) the frequency excitation profile due to the pulse. The frequency profile is the Fourier transform of the time profile.

Modern high resolution spectrometers typically have 90° pulses of duration $10\mu\text{s}$ or less. While this allows excitation over a 200 kHz spectral window, it is important to have near uniform excitation over the entire spectral window. A $10\mu\text{s}$ pulse provides near uniform excitation over $\sim 25\text{ kHz}$, which is adequate for most high resolution applications. However, solid state spectra have much wider spectral windows, requiring much shorter pulses.

After the pulse generates x - y magnetization, the return of this magnetization to equilibrium is sampled as a function of time. This response is called the free induction decay (FID) signal. In the vector model, it can be regarded as the resultant of a series of individual magnetization vectors, each precessing in the x - y plane at some frequency $\Delta\nu$ relative to the transmitter frequency

and decaying exponentially with a time constant T_2 , characteristic of the return to equilibrium of x - y magnetization. Each vector corresponds to a specific signal in the frequency spectrum, and thus the Fourier transform of the FID yields the frequency spectrum:

$$\begin{aligned} F(\nu) &= \int_{-\infty}^{+\infty} f(t) \exp(2\pi i \nu t) dt \\ &= \int_{-\infty}^{+\infty} f(t) [\cos(2\pi \nu t) + i \sin(2\pi \nu t)] dt \quad [3] \end{aligned}$$

This is illustrated in **Figure 4** for a spectrum of a single off-resonance peak. **Figure 5** shows the FID and frequency spectrum for the aliphatic region of kauradienoic acid [1].

[1]

The two basic types of signals that can be detected in an NMR experiment (**Figure 6**) are an absorption signal (owing to detection of a signal at right angles to B_1) and a dispersion signal (owing to a signal parallel to B_1), corresponding to the cosine and sine terms in eqn [3]. The phase for an on-resonance (i.e. $\Delta\nu = 0$) peak can easily be adjusted to give an absorption signal via a zero frequency phase adjustment.

However, off-resonance peaks undergo additional phase shifts due to vector evolution during the finite pulse and the delay between the pulse and gating on the receiver (see **Figure 3**). For example, for a total time before acquisition of $20\ \mu\text{s}$, a peak at $\Delta\nu = 10\,000\ \text{Hz}$ will rotate through an angle:

$$\begin{aligned} \alpha &= 2\pi(2.0 \times 10^{-5})(1.0 \times 10^4) \text{ radians} \\ &= 0.40\pi \text{ radians} = 72^\circ \quad [4] \end{aligned}$$

introducing a significant dispersive component. Fortunately, this phase shift varies linearly with $\Delta\nu$ and thus can be corrected by applying a phase correction which varies linearly with frequency.

The acquisition time, t_1 , is determined by the time required for x - y magnetization to decay to near zero as

well as by the desired data point resolution. Typical values for one-dimensional spectra range from 0.5 to 5 s. The ability to excite and acquire all signals for a given nucleus simultaneously provides a major sensitivity advantage over the older continuous wave (CW) method which involved slowly sweeping through the spectral window, exciting one signal at a time. Typically, one can acquire at least 100 FID signals in the time taken to acquire a CW spectrum. Since the signal-to-noise increases as the square root of the number of scans, this provides at least a 10-fold increase in sensitivity.

However, the acquisition of multiscan spectra introduces a new problem. Ideally, M should have returned to its equilibrium position along the $+z$ -axis before the next pulse. Otherwise, the residual magnetization will fractionally decrease with each scan, a phenomenon known as saturation. Compounding the problem is the fact that the time constant for return to equilibrium along the z -axis, T_1 , can be longer than T_2 (see below). One

solution is to introduce an additional relaxation delay between the end of each acquisition and the next pulse. The second is to use a shorter pulse duration so that the rotation angle of M , α , is $< 90^\circ$. Richard Ernst conclusively demonstrated that the second approach gives a superior signal-to-noise ratio. The ideal pulse flip angle, α_E , called the Ernst angle, is given by:

$$\cos \alpha_E = \exp(-t_1/T_1) \quad [5]$$

Figure 7 Comparison of $z(M_z)$ and $y(M_y)$ magnetization immediately following (a) a 90° pulse and (b) a 45° pulse. The latter generates 71% of the amount of M_y magnetization (and therefore 71% of the signal) while retaining 71% of equilibrium z magnetization, compared with 0_z magnetization after a 90° pulse. This allows most, if not all, of the equilibrium z magnetization to be restored during the acquisition time, t_1 , after a 45° pulse while a 90° pulse typically will require a lengthy delay after t_1 to restore equilibrium z magnetization. If T_1 is very long compared with t_1 , an even smaller pulse angle must be used (see eqn [5]).

This is illustrated in Figure 7, using a simple trigonometric argument. However, T_1 may be significantly different for different peaks in a spectrum (e.g. a ^{13}C spectrum of a molecule containing protonated and non-protonated carbons). This requires a compromise choice of α and relative peak areas may no longer be quantitative.

Finally, the analogue voltage signal detected by the receiver must be digitized for computer storage and processing. This puts some constraints on data acquisition, as discussed in any of the texts listed in the Further Reading section.

Measurement of T_1 and T_2 Relaxation Times

The classical equations for the return of magnetization to equilibrium along the z - and y -axes are respectively:

$$\frac{dM_z}{dt} = -(M_z - M_0)/T_1 \quad \text{and} \quad \frac{dM_y}{dt} = -M_y/T_2 \quad [6]$$

where M_0 is the magnitude of equilibrium z magnetization. The spin-lattice or longitudinal relaxation time, T_1 , reflects the effect of the component of the random fluctuating magnetic field (arising from the thermal motion of dipoles in the sample) at the Larmor frequency. However, the spin-spin or transverse relaxation time, T_2 , is also affected by static magnetic field components, including any inhomogeneity of the magnetic field over the region of the sample. Consequently, transverse relaxation is in principle faster than longitudinal relaxation, i.e. T_2 can be smaller than T_1 .

The inversion-recovery sequence can be used to measure T_1 (Figure 8). The 180° pulse inverts the equilibrium magnetization M . During the delay t_1 , the magnetization begins to return to equilibrium. A 90°_x pulse then samples the magnetization remaining after t_1 . Since the final pulse is a 90° pulse, it is necessary to

include a relaxation delay, Δ , to allow for return to equilibrium between scans. Ideally $\Delta \geq 5T_1$. However, it has been found that accurate values of T_1 can still be obtained using shorter values of Δ , known as the fast inversion-recovery method. After a sufficient number of scans, n , have been collected to achieve adequate signal-to-noise, the experiment is repeated, systematically varying t_1 from small values out to $\sim 2T_1$. The intensity of each peak exponentially returns to equilibrium as t_1 increases (Figure 8). T_1 can be determined from a least-squares fit of the equation

$$\ln [S_\infty - S(t_1)] = \ln 2 + \ln S_\infty - t_1/T_1 \quad [7]$$

This gives a linear plot of slope $-1/T_1$. However, this approach is particularly sensitive to errors in S_∞ (obtained with $t_1 \geq 5T_1$). The alternative, more reliable, approach is to carry out an exponential fit to each relaxation curve. This does not require an accurate value of S_∞ and is well suited to the fast inversion-recovery method.

The value of T_2 can be determined from the line width of a signal at half of its maximum height:

$$\Delta\nu_{1/2} = (\pi T_2)^{-1} \quad [8]$$

However, this includes any contribution to the line width from magnetic field inhomogeneity. A 'true' T_2 ,

Figure 8 (a) The inversion-recovery sequence used to measure T_1 . The experiment is repeated with a number of different values of t_1 . (c) A plot of signal intensity (s) versus t_1 , illustrating the exponential return to the equilibrium value, S_∞ , as t_1 increases.

independent of contributions from field inhomogeneity, can be obtained with the aid of a spin-echo or refocusing pulse sequence (Figure 9). This pulse sequence also forms a key component of many other multipulse experiments. Consider a single magnetization vector which is off-resonance by $\Delta\nu$ Hz, because of chemical shift effects or field inhomogeneity. After the initial 90°_x pulse rotates it to the y -axis, it precesses during $t_1/2$ at angular velocity $2\pi\Delta\nu$ rad s^{-1} , rotating through an angle α . The 180°_y pulse 'flips' it from the positive to the negative x region (or vice versa) so that it is now at an angle $-\alpha$ with respect to the y -axis. During the second $t_1/2$ period it again rotates through α , returning the vector to the y -axis, i.e. it is refocused (see Figure 9). The FID is then collected. The spin-echo sequence can be repeated a number of times, systematically varying t_1 . Alternatively, one can generate an echo train in a single experiment, applying a 180°_y pulse at $t_1/2$, $3t_1/2$, $5t_1/2$, etc. and sampling the FID at the peaks of the echoes produced at t_1 , $2t_1$, $4t_1$, etc. In either case, an exponential fitting process can be used to determine T_2 from the variation in signal intensity as a function of t_1 .

heteronuclear spectrum in terms of the number of bonded hydrogens. There are three basic sequences which fall into two distinct classes. The first is the APT sequence which involves initial ^{13}C excitation and ^{13}C detection. Figure 10 illustrates the multiplet patterns expected for ^{13}C peaks coupled to 0, 1, 2 and 3 hydrogens. Now consider the effect of the APT pulse sequence (Figure 11) upon a ^{13}C - ^1H spin system. In the vector model, the ^{13}C magnetization is excess α spin. This can be divided into two nearly equal magnetic vectors, corresponding to ^{13}C α spin bonded to either ^1H α or β spins. Following the initial 90°_x pulse, these two vectors begin to precess in the x - y plane with angular velocities $2\pi(\Delta\nu \pm J/2)$, where $\Delta\nu$ is the chemical shift (in Hz), relative to the transmitter, and $J = {}^1J_{\text{CH}}$, the one-bond ^{13}C - ^1H coupling constant. After $t_1/2$, the 180°_y ^{13}C pulse flips the vectors about the y -axis. The simultaneous 180° ^1H pulse inverts the equilibrium (z) ^1H magnetization, interchanging ^1H α and β spin states. The two vectors continue to precess during the second $t_1/2$ period. At the end of this period, they are at angles with respect to the y -axis given by:

$$\alpha = \pm(2\pi J/2)t_1 = \pm\pi Jt_1 \quad [9]$$

Spectral Editing Pulse Sequences

These pulse sequences, which are important in ^{13}C NMR spectroscopy, allow assignment of individual peaks in a

Thus, the ^{13}C chemical shift is refocused by the ^{13}C 180° pulse while the pair of 180° pulses allow ${}^1J_{\text{CH}}$ to evolve through t_1 . Applying ^1H decoupling during acquisition

Figure 9 (a) The spin-echo or refocusing sequence for measuring T_2 . (b) Behaviour of a magnetization vector, corresponding to an off-resonance ($\Delta\nu \neq 0$) signal, during the spin-echo sequence. (c) The vector returns to the initial position after t_1 , producing an 'echo'.

Figure 10 Multiplet patterns arising from $^1J_{\text{CH}}$ (one-bond ^{13}C – ^1H coupling constant) in the ^{13}C spectra of CH_n groups ($n=0$ – 3).

rapidly scrambles ^1H spin states, producing a single, averaged vector which initially is along the y -axis but precesses at a frequency $\Delta\nu$ during FID acquisition. This results in a peak at $\Delta\nu$ in the frequency spectrum with an intensity determined by the vector average at the end of t_1 . **Table 1** summarizes the results for CH_0 , CH_1 , CH_2 and CH_3 peaks for different values of t_1 . Only a CH_0 peak is observed at $t_1 = 1/2J$ since the coupling vectors for the other multiplets average to zero. For $t_1 = 1/J$, CH_0 and CH_2 peaks are positive (upright) while CH_1 and CH_3 peaks are negative (inverted). This allows partial assignment of carbons in terms of numbers of attached protons. The main weakness of this approach is that it is sensitive to variations in $^1J_{\text{CH}}$ and thus may give unreliable results for compounds which have a wide range of $^1J_{\text{CH}}$ for carbons.

The other two spectral editing sequences are insensitive nuclei enhanced by polarization transfer (INEPT) and distortionless enhancements by polarization transfer (DEPT) (see **Figure 12**). Both of these sequences involve ^1H excitation, followed by magnetization transfer to the heteronucleus by a mechanism called polarization transfer. This provides heteronuclear signal enhancement by a factor of $\gamma_{\text{H}}/\gamma_{\text{X}}$, e.g. ~ 4 for ^{13}C . In the case of INEPT, this can be adequately described by the vector model in terms of selective inversion of the populations of ^1H energy levels corresponding to carbons in the α spin state. However, although the sequences appear similar, DEPT can only be explained by a quantum mechanical model.

The two sequences use different forms of spectral editing. With INEPT, this is done by the choice of the

Figure 11 (a) The APT (attached proton test) pulse sequence. (b) Behaviour of the ^{13}C magnetization due to a ^{13}C – ^1H spin pair during the APT sequence. The two components, corresponding to ^1H in α or β spin states, precess at frequencies $\Delta\nu \pm J/2$ (where $J = ^1J_{\text{CH}}$). The spin-echo sequence refocuses the chemical shift ($\Delta\nu$) but not J (see eqn [9]). This figure illustrates the result when $t_1 = J/2$ with vectors rotating through $\alpha = \pm\pi/2$.

final delay. If $\Delta_3 = J/2$, only CH carbons appear while $\Delta_3 = 3J/4$ produces a spectrum with CH and CH_3 up and CH_2 down. With DEPT, editing is carried out by varying the angle of the final ^1H pulse; $\Theta = 90^\circ$ yields only CH carbons while $\Theta = 135^\circ$ yields CH and CH_3 up and CH_2 down. Because it relies on a pulse angle rather than a delay, DEPT is less sensitive than INEPT to variations in $^1J_{\text{CH}}$ and is thus the sequence of choice. Note that residual ^{13}C magnetization is suppressed by phase cycling in each case (see below) and thus non-protonated carbons are not observed with either sequence.

Phase Cycling for Artifact Suppression

Before the development of pulsed field gradient sequences (see below), most NMR pulse sequences included a phase

Table 1 Vector evolution for various CH_n ($n=0-3$) multiplets and resultant vectors at the end of t_1 for the APT sequence with various values of t_1

These are calculated from the frequencies in **Figure 10** plus eqn [12].^dVector average, relative to y -axis, of coupling vectors relative to an initial value of 1.00. Effects of T_2 relaxation during t_1 are not included.**Figure 12** (a) INEPT pulse sequence. (b) DEPT pulse sequence. The article on product operator formalism describes the behaviour of the DEPT sequence while the texts by Harris and Günther (see Further Reading section) describe the behaviour of INEPT in terms of vector diagrams and energy levels.

cycle in which the phases of at least one pulse and the receiver were varied systematically. This was needed for one or more of several reasons, e.g. suppression of unwanted signals, suppression of artifacts due to hardware imperfections and/or incomplete return to equilibrium between scans and coherence pathway selection in multi-dimensional NMR. One example of each of the first two kinds of phase cycle is briefly discussed below.

In the INEPT sequence (**Figure 12**), the final 90_y ${}^1\text{H}$ pulse sets up selective inversion of the populations of a pair of levels within the coupled AX (${}^1\text{H}$ - ${}^{13}\text{C}$) spin system. The 90_y ${}^{13}\text{C}$ pulse then generates two antiphase magnetization vectors of relative intensity $+4$ and -4 (relative to equilibrium ${}^{13}\text{C}$ magnetization) along the $\pm x$ -axes owing to magnetization (polarization) transfer from ${}^1\text{H}$ arising from the selective population inversion.

However, the ${}^{13}\text{C}$ 90_y pulse also generates a magnetization vector from the initial ${}^{13}\text{C}$ magnetization. It is desirable to eliminate the latter component to avoid complications with spectral editing. This is done by alternating the phase of the final ${}^1\text{H}$ pulse 90_y , 90_{-y} while alternately adding and subtracting FID signals. With the 90_{-y} pulse, the antiphase ${}^{13}\text{C}$ vectors become -4 , $+4$ but this is converted back into $+4$, -4 by subtracting this FID. However, the ${}^{13}\text{C}$ 90_{-y} pulse always generates a signal of the same phase owing to ${}^{13}\text{C}$ magnetization and thus is cancelled by the alternate addition and subtraction of FID signals.

Quadrature detection involves the use of two receivers. If the two receivers have different gains, 'quadrature image' peaks are generated at $-\Delta\nu$ for every true peak at $+\Delta\nu$. This can be eliminated by using a four-step

CYCLOPS phase cycle in which the phase of a transmitter is cycled through relative phases $x, y, -x, -y$ along with the receiver. Derome (see Further Reading) gives a very clear account of quadrature images and how they are suppressed by CYCLOPS phase cycling.

Quantum Mechanical Methods for Understanding Pulse Sequences

The ultimate approach for interpreting multipulse sequences and their resultant spectra is a full density matrix treatment. While this approach is ideal for simulating the spectrum generated by a multipulse experiment, the calculations are complex and do not provide obvious physical insights. A very useful and widely used simplified quantum mechanical approach involves product operator formalism. This focuses on the components of the density matrix which are directly relevant to the experiment. Product operator descriptions of several of the pulse sequences discussed here are given in another article.

Mastery of this approach is essential for anyone desiring to design new pulse sequence experiments and valuable for anyone wishing to understand modern NMR experiments.

Multidimensional NMR Experiments

Multidimensional NMR experiments have revolutionized the use of NMR spectroscopy for the structure determination of everything from small molecules to complex proteins. Since most of the 3D and 4D experiments are essentially combinations of two-dimensional (2D) experiments, this section will focus on 2D NMR. Only a basic overview will be given since many specific multidimensional experiments are discussed elsewhere.

Two-Dimensional NMR Spectroscopy

A generalized 2D experiment is illustrated in **Figure 13**. The preparation time is usually a relaxation delay followed by one or more pulses to start the experiment. The evolution period establishes the second frequency dimension. A series of FID signals are collected with t_1 regularly incremented from 0 up to the desired

maximum value, $t_1(\text{max})$. The number of increments and $t_1(\text{max})$ depend on the desired spectral width and data point resolution along the time-incremented axis. Depending on the experiment, the evolution period may contain one or more pulses, most commonly a spin-echo sequence. The mixing period, which is not required in some sequences, can be a 90° mixing pulse, a fixed delay, a more complex pulse such as a spin lock or isotropic mixing pulse or some combination of these. Finally, data is acquired during t_2 , as in a 1D experiment. Double Fourier transformation, with respect to t_2 then t_1 , yields a spectrum with two orthogonal frequency scales.

2D NMR experiments are designed to generate different kinds of frequency information along the two axes. The principle behind this frequency separation is most easily seen by considering modification of the APT sequence (**Figure 11**) to produce a 2D sequence, the heteronuclear J -resolved sequence. This involves replacing the constant t_1 period by an incremented t_1 period. Each ^{13}C signal in f_2 is then modulated by the evolution of $^1J_{\text{CH}}$ coupling vectors as t_1 is incremented (e.g. see **Table 1**). Fourier transformation with respect to t_1 at each f_2 frequency then produces a 2D spectrum where a cross section through each ^{13}C peak in f_2 will give a $^1J_{\text{CH}}$ multiplet pattern similar to one of those shown in **Figure 10**. Similarly, the INEPT sequence can be converted into a 2D sequence (the heteronuclear shift correlation sequence or HETCOR) by inserting a spin-echo sequence, $t_1/2 - 180^\circ(\text{C}) - t_1/2$ immediately after the initial ^1H 90° pulse (see **Figure 12**). The extent of polarization transfer from ^1H to ^{13}C is then modulated by ^1H chemical shift evolution as t_1 is incremented, with the resultant 2D experiment having ^{13}C chemical shifts along f_2 and ^1H chemical shifts along f_1 .

High-resolution 2D NMR pulse sequences can be based on information transfer via homonuclear or heteronuclear scalar coupling, dipolar relaxation or chemical exchange while solid-state 2D NMR experiments normally use dipolar coupling in place of scalar coupling. There are three basic modes of spectral display: with the normal spectrum along the diagonal and off-diagonal peaks for correlated signals (see COSY spectrum, **Figure 14**), different chemical shift information along the two axes (e.g. ^1H and ^{13}C or ^{15}N , see **Figure 15**) and spectra with single quantum frequencies along f_2 and multiple quantum frequencies along f_1 . The characteristics of many of the common high resolution 2D sequences are summarized in **Table 2**.

However, the real strength of multidimensional NMR is not in the information provided by a single experiment but rather in the synergy provided by carrying out several different experiments on the same molecule. This is illustrated below for kauradienoic acid [1], one of the very first molecules where combined 2D methods were used for spectral assignment. The ^1H - ^1H COSY spectrum

Figure 13 A general two-dimensional NMR pulse sequence. Data are acquired during t_2 for a series of spectra in which t_1 is regularly incremented from 0 to some maximum value. Fourier transformation with respect to t_2 and then t_1 generates a spectrum with two different frequency axes.

Figure 14 (a) The COSY pulse sequence. (b) The COSY spectrum for the aliphatic region of [1], showing the ${}^1\text{H}$ spectrum along the diagonal and symmetric off-diagonal peaks between coupled protons. The connections for one molecular fragment $[\text{C}(5)\text{H}-\text{C}(6)\text{H}_2-\text{C}(7)\text{H}_2]$ are traced out.

(Figure 14) and the ${}^1\text{H}-{}^{13}\text{C}$ shift correlation spectrum (Figure 15) for [1] allow assignment of molecular fragments involving sequences of protonated carbons. Further experiments allow completion of the structural and spectral assignments (see caption to Figure 15).

Absolute Value versus Phase Sensitive 2D Spectra

Many of the original 2D sequences gave spectra which could not be phased since they involved different mixtures of absorption and dispersion modes for different peaks. To simplify displays, these spectra were plotted in absolute value mode, $(u^2 + v^2)^{1/2}$, where u refers to dispersion mode and v to absorption mode. While the individual absolute value mode peaks appear to be properly phased, they are distorted from Lorentzian shape with broad tails. Better resolution and sensitivity can be obtained if spectra are obtained in a manner which provides pure absorption mode peaks. There are now

phase sensitive versions of most 2D sequences. There are two requirements for obtaining phase sensitive spectra. First, any fixed delay must include a spin-echo sequence to prevent chemical shift evolution. Second, one must acquire two separate data sets with one of the pulses having a 90° phase difference for the two spectra or one must increment the phase of one of the pulses by 90° with each time increment while doubling the number of time increments collected.

Phase Cycling for Coherence Pathway Selection in 2D NMR

This important topic can only be understood in quantum mechanical terms. Owing to space limitations, only a very brief introduction can be given here.

The COSY sequence (Figure 14) will be used to illustrate the concept. A coherence level diagram for this sequence is given in Figure 16. Equilibrium z magnetization is defined as having a coherence level of 0. The

Figure 15 (a) The basic HSQC (heteronuclear single quantum coherence) pulse sequence. (b) The HSQC spectrum of the aliphatic region of [1] with the ^{13}C along f_1 and the ^1H spectrum along f_2 . The ^{13}C – ^1H connectivities are marked for the same molecular fragment as in **Figure 14**. Other sequences of protonated carbons can be determined from the same spectrum while an n -bond ($n=2,3$) ^{13}C – ^1H shift correlation spectrum such as HMBC, COLOC or FLOCK (see **Table 2**) can identify non-protonated carbons and tie together the molecular fragments into a complete structure.

90° pulse acts as a raising or lowering operator, i.e. it can change the spin quantum number of an individual nucleus by ± 1 , resulting in the generation of observable x,y magnetization. This evolves during t_1 at frequencies determined by the chemical shift and homonuclear coupling. The second 90° pulse then can generate further coherence level changes, including level changes of 0 to ± 2 associated with a pair of coupled nuclei. The receiver can only detect single quantum coherence and is chosen to be at coherence level $+1$. Thus, a pair of ideal pulses can generate a COSY signal by two paths with coherence level changes $+1, 0$ or $-1, +2$, respectively called P (or antiecho) and N (echo) signals. If both paths are detected, signals will occur at both $+\Delta\nu_1$ and $-\Delta\nu_1$ along the f_1 axis. However, phase cycling allows one to choose one path, rejecting the other. The change in coherence phase associated with a pulse is given by:

$$\Delta\theta = \Delta p \cdot \Delta\phi \quad [10]$$

Table 2 Characteristics of several commonly used 2D NMR pulse sequences

Sequence	Display mode ^a	f_1, f_2^b	Transmission ^c
COSY	D, OD	$\delta_{\text{H}}, \delta_{\text{H}}$	J_{HH}

HSQC ⁱ	f_1, f_2	$\delta_{\text{X}}, \delta_{\text{H}}$	$^1J_{\text{CH}}$
HMBC ⁱ	f_1, f_2	$\delta_{\text{X}}, \delta_{\text{H}}$	$^nJ_{\text{CH}}$
INADEQUATE	DQ, SQ	$\delta_{\text{C}(1)} + \delta_{\text{C}(2)}, \delta_{\text{C}(1)}$	$^1J_{\text{CC}}$

^aD, OD: spectrum along diagonal with off-diagonal peaks between correlated protons, e.g. see COSY spectrum (**Figure 14**), f_1, f_2 : different chemical shift scales along f_1, f_2 , e.g. see HSQC spectrum (**Figure 15**), DQ, SQ: double quantum frequencies along f_1 (sum of frequencies of coupled ^{13}C peaks, relative to transmitter), regular (single quantum) ^{13}C spectrum along f_2 .

^bChemical shift information appearing along each axis. [δ scale $\equiv$ chemical shift in parts per million relative to internal reference [$\delta_1(\text{CH}_3)_4$ for ^1H , ^{13}C and ^{29}Si]]. Note that the ^1H -axis normally also shows multiplet structure owing to J_{HH} .

^cParameter by which information is transmitted to establish correlations between the spectra on the two frequency axes: $J_{\text{HH}} = ^1\text{H}$ – ^1H coupling constant, $H_{\text{A}} \rightleftharpoons H_{\text{B}}$ is chemical exchange between different sites, $J_{\text{CH}} =$ one-bond ^{13}C – ^1H coupling constant, $^nJ_{\text{CH}} = n$ -bond ($n=2$ or 3) ^{13}C – ^1H coupling constant, $^1J_{\text{CC}} =$ one-bond ^{13}C – ^{13}C coupling constant.

^dDQCOSY $\equiv$ double quantum filtered COSY. This suppresses strong singlets (e.g. solvent peaks) and gives well-resolved off-diagonal peaks with up–down intensity patterns for coupled protons, i.e. those giving rise to the off-diagonal peak.

^eTOCSY (also called HOHAHA) relays information among sequences of coupled protons. A cross section through the f_2 frequency of a specific proton shows f_1 peaks for all of the protons within the coupled sequence.

^fROESY $\equiv$ NOESY in the rotating frame.

^gThe EXSY sequence is identical to the NOESY sequence but detects cross peaks between chemically exchanging hydrogens. Both EXSY and NOESY peaks may appear in the same spectrum.

^hX nucleus (usually ^{13}C) detected heteronuclear shift correlation sequences.

ⁱ ^1H detected heteronuclear shift correlation sequences. These are more sensitive than the earlier X-nucleus detected sequences [by $(\gamma_{\text{H}}/\gamma_{\text{X}})^{3/2}$] but have more limited resolution along the $X(f_1)$ axis.

Figure 16 Coherence level diagram for the COSY sequence. The symbols N and P designate the N and P pathways.

where $\Delta\theta$ is the change in coherence phase (in increments of $\pi/2$), $\Delta\rho$ is the change in coherence level and $\Delta\phi$ is the change in pulse phase (in units of $\pi/2$). **Table 3** shows how this can be used to design two-step phase cycles for a coherence pathway section with the COSY sequence.

The dotted line indicates a third possible coherence pathway. If the initial 90° pulse is imperfect, there will be some residual z magnetization which will be raised to coherence level $+1$ by the second 90° pulse. Suppression of this pathway requires two extra steps, yielding a four-step phase cycle. Finally, if one also wishes to incorporate a CYCLOPS cycle for f_2 quadrature image suppression, the total phase cycle is $4 \times 4 = 16$ steps. The number of scans in a 2D experiment should be some whole number multiple of the number of steps in the phase cycle. However, with COSY, the sensitivity is high enough that 16 scans are usually more than necessary to acquire good spectra and thus the phase cycle determines the minimum time for the experiment. Fortunately, pulsed field gradient sequences have overcome this problem.

Gradient Pulse Sequences

Many of the pulse sequences discussed above now have versions which incorporate magnetic field gradient pulses that can be used to replace phase cycling. They allow one to acquire a spectrum in greatly reduced time and/or with greatly reduced artifacts. For example, applying two identical field gradient pulses before and after the final 90° pulse in COSY selects the N (echo) path while suppressing the other paths.

Pulse Sequences Which Replace Single Pulses

A number of pulse ‘sandwiches’ have been developed to replace single pulses in specific cases. These include the following.

Composite 180° Pulses

The quality of the spectra obtained with many pulse sequences is strongly dependent on the precision of 180° pulses, particularly in the case of 180° inversion pulses for heteronuclei with broad spectral windows. Problems can arise due to mis-set pulses, inhomogeneity in pulses over the sample or incomplete excitation at large frequencies relative to the transmitter. These problems can be minimized by the use of composite 180° pulses, e.g. a 90_x° , 180_y° , 90_x° composite pulse in place of a 180_x° pulse (**Figure 17**).

BIRD (Bilinear Rotating Decoupling) Pulses

BIRD pulses act as selective 180° ^1H pulses for either protons directly bonded to ^{13}C or not bonded to ^{13}C , while simultaneously providing a ^{13}C 180° pulse (**Figure 18**). Earlier uses of these pulses included partial ^1H – ^1H decoupling in HETCOR and optimization of performance of long-range ^{13}C –detected ^{13}C – ^1H correlation sequences such as COLOC and FLOCK. The most common current use is for suppression of ^1H – ^{12}C magnetization in ^1H –detected one-bond ^{13}C – ^1H correlation sequence, i.e. HMQC and HSQC. Although BIRD pulses can be explained by vector diagrams (**Figure 18**), a full understanding of these pulses requires a quantum mechanical treatment.

Frequency Selective Pulses

The ability to selectively excite a narrow spectral region is important both for solvent suppression and because it often allows one to replace a full 2D experiment by a limited number of 1D experiments. A ‘soft’ (i.e. low power, long duration) pulse can be used for selective excitation but this does not generate uniform excitation but this does not generate uniform excitation (see **Figure 3**). Better results are obtained from multiple pulse sequences. Modern spectrometers allow the generation of ‘shaped’ pulses whose time profiles are designed to produce the desired excitation profiles. A series of pulses of controlled amplitude, duration and phase (without intervening delays) are used which provide the desired profile. For example, generating a pulse with a

Figure 17 (a) Vector diagram illustrating the effect when a nominal 180° pulse is mis-set, resulting in only 170° rotation. (b) Illustration of how a composite 90_x° , 180_y° , 90_x° compensates for the effect of a mis-set pulse. Compensation is less complete for off-resonance signals.

Figure 18 (a) The BIRD pulse sequence and effects of different combinations of phases within the BIRD pulse. (b) Vector diagram for a ^{12}C - ^1H spin system, illustrating how 90°_x , 180°_y , 90°_x and 90°_x , 180°_y , 90°_x BIRD pulses, respectively, act as 180° and 0° ^1H pulses. Since the BIRD pulse corresponds to the APT sequence (with ^1H and ^{13}C pulses interchanged) up to the point of the final 90° pulse, the effect of these two BIRD pulses on a ^1H - ^{13}C pair can be deduced from the data in **Table 1** for $n = 1$. With $\Delta = 1/J_{\text{CH}}$, the vectors associated with the ^1H - ^{13}C pair are refocused along the $-y$ -axis and a 90°_x pulse will rotate them back to the z -axis (0° pulse) while a 90°_{-x} pulse rotates them to the $-z$ -axis (180° pulse).

time profile similar to the frequency profile in **Figure 3** will give a narrow square wave excitation profile. Both 90° and 180° pulses can be generated as well as pulses which simultaneously irradiate at two or more chosen frequencies. The bandwidth of each pulse can be adjusted to selectively irradiate a chosen signal or to cover a specific spectral region (e.g. irradiation of the amide $^{13}\text{C}=\text{O}$ region in a 3D or 4D protein spectrum).

Broad-Band Decoupling Pulse Sequences

Multiple pulse sequences can also be used to provide effective broad-band decoupling. The original pulse sequence of this kind was the WAHUHA sequence of Waugh and co-workers which was designed to minimize broadening arising from homonuclear dipolar coupling in solid-state spectra.

For high-resolution NMR, the main interest has been in heteronuclear broad-band decoupling. Initially, the interest was in broad-band ^1H decoupling while acquiring heteronuclear (e.g. ^{13}C) spectra. More recently, with the increasing use of ^1H -detected 2D, 3D and 4D sequences involving ^1H -X chemical shift correlation, the emphasis has been on decoupling of heteronuclei (e.g. ^{13}C , ^{15}N). This is much more demanding owing to the much wider heteronuclear chemical shift window. Increasingly effective decoupler pulse sequences have been developed with acronyms such as MLEV, WALTZ, GARP, DIPSI and WURST. Most are based on a composite 180° decoupler pulse which is subjected to a series of phase cycles. For example, WALTZ is based on a 90°_x , 180°_{-x} , 270°_x composite pulse (which in shorthand form is designated 1 2 3, justifying the name WALTZ).

Table 3 Alternative two-step phase cycles for N-type pathway selection and P-pathway suppression for a COSY spectrum plus a four-step phase cycle which selects the N-pathway while suppressing both P and Z paths

	N		P			N		P

$\phi(R)$ ^c	0	1	2	3		0	1	2	3

^aPulse and receiver phases x , y , $-x$ and $-y$ are, respectively, given as 0, 1, 2 and 3, corresponding to the number of $\pi/2$ phase increments relative to a 90° pulse.

^b $\Delta p = -1$ for the coherence level change in the N pathway while $\Delta\theta(P1) = 3$. From eqn [10], $\Delta p \Delta\theta = (-1)(3) = -3$. However, since a -270° phase shift corresponds to a -90° phase shift, $-3 \equiv 1$.

^c $\phi(R)$ = receiver phase. When the sums of coherence phase changes in different scans match the receiver phase cycle, successive scans add, while when the relative phases change 0, 2 successive scans cancel. Thus in each case, the signals from the N path add while signals from the P path cancel.

^dAn alternative four-step phase cycle for N-path selection involves a $\phi(P1) = 0, 1, 2, 3$ and $\phi(R) = 0, 3, 2, 1$. For P-type selection $\phi(P1)$ and $\phi(R)$ should either both be 0, 1, 2, 3 or both be 0, 3, 2, 1. Another alternative for N-pathway selection is to expand the first two-step phase cycle to a four-step cycle with $\phi(P2) = 0, 1, 2, 3$ and $\phi(R) = 0, 2, 0, 2$.

^eIn this four-step phase cycle, the P-pathway is cancelled in steps 1 + 2 and in steps 3 + 4 while the Z pathway is cancelled in steps 1 + 3 and steps 2 + 4.

The symbols N and P indicate the coherence level change from the first pulse and are respectively negative (-1) and positive ($+1$) for the two paths. The third path, from an imperfect initial 90° pulse, has zero coherence level change in the initial pulse and is thus given the symbol Z.

Summary

This article has given an overview of the many different multiple pulse experiments which have developed from the original pulse Fourier transform experiment. These experiments, along with major improvements in spectrometer instrumentation, have dramatically increased the range of structural and dynamic problems that can be studied by NMR spectroscopy.

Symbols

B_1	RF field along an axis of the rotating frame
C	spin–rotation interaction tensor
$d'_{mn}(\Omega)$	reduced Wigner rotation matrix elements
$D'_{mn}(\Omega)$	Wigner rotation matrix elements
eQ	nuclear electric quadrupole moment
eq	electric field gradient at nucleus
$g_{mn}(t)$	reduced time correlation function
$G_m(t)$	time correlation function of spin coupling tensor
H_0	static spin Hamiltonian
$H(t)$	zero-average, time-dependent spin Hamiltonian
$H_q(t)$	q th component of time-dependent spin Hamiltonian
I	nuclear spin angular momentum
I_m	moment of inertia
J	scalar coupling constant
$J_n(n\omega_0)$	spectral density of the n th component of a fluctuating coupling tensor at frequency $n\omega_0$
P_α	population of the spin state $ \alpha\rangle$
r_{ij}	internuclear distance
R	Redfield relaxation supermatrix
$R_{\alpha\alpha'\beta\beta'}$	Redfield relaxation supermatrix elements
T_{1Z}	longitudinal or Zeeman spin–lattice relaxation time
T_{1D}	dipolar spin–lattice relaxation time
T_{1Q}	quadrupole spin–lattice relaxation time
T_{1T}	longitudinal relaxation time due to translation
$T_{1\rho}$	rotating frame spin–lattice relaxation time
$T_{2,m}$	spin operator tensor
T_2	transverse or spin–spin relaxation time
γ	nuclear gyromagnetic ratio
η	asymmetry parameter of electric field gradient tensor
σ	chemical-shift tensor
$\tilde{\alpha}$	density operator in the <i>interaction</i> representation
τ_c	correlation time

τ_J	angular momentum correlation time
τ_s	scalar relaxation correlation time
ψ	wavefunction
ω_D	average dipolar coupling expressed as a frequency
ω_0	Larmor precession frequency
ω_Q	average quadrupole coupling expressed as a frequency
$\Omega(\frac{1}{2}\alpha, \beta, \gamma)$	Euler angles
$90^\circ_x, 45^\circ_y$	RF pulses producing rotations of 90° , 45° about the x , y axes of the rotating frame

How a nuclear spin system achieves thermal equilibrium by exchanging energy with its surrounding medium or the ‘lattice’ is governed by the NMR relaxation rates. The lattice consists of all degrees of freedom, except those of the nuclear spins, associated with the physical system of interest. Pulsed NMR provides a highly versatile and flexible tool to determine spin relaxation rates, which can probe the entire spectrum of molecular motions. These include molecular rotation, translational self-diffusion, ‘coherent’ rotational motion, and the internal motion in nonrigid molecules. Physical systems investigated by NMR range from condensed matter phases to dilute molecular gases. The theory of nuclear spin relaxation is now well understood, and the details are given in the classical treatise by Abragam. An elementary treatment of the same material can be found in the text by Farrar. In relating the measured spin relaxation rates to molecular behaviours, there are severe limitations and difficulties that a newcomer can often fail to appreciate. Several nuclear interactions may simultaneously all contribute to the relaxation of a spin system. These may include the magnetic dipole–dipole interaction, the quadrupole interaction, the spin–rotation interaction, the scalar coupling of the first and second kind, and the chemical-shift anisotropy interaction. Due to the need of estimating certain nuclear couplings and/or correlation times associated with molecular motions, considerable uncertainty may exist in identifying and separating these contributions. The semiclassical relaxation theory of Redfield is outlined in this short review to give expressions of spin relaxation rates in terms of spectral densities of motion. The treatment is

semiclassical simply because it uses time correlation functions which are classical.

The most difficult problem in any relaxation theory is the calculation of correlation functions or spectral densities of motion. It is often possible to determine the mean square spin interaction $\langle H_q^2(t) \rangle$, where $H_q(t)$ is a component of the spin Hamiltonian which fluctuates randomly in time owing to molecular motions. The time dependence of the correlation function $\langle H_q(t)H_q(t-\tau) \rangle$ can often be approximated by an exponential decay function of τ , i.e.

$$\langle H_q(t)H_q(t-\tau) \rangle = \langle H_q(t)H_q(t) \rangle \exp(-\tau/\tau_c) \quad [1]$$

where the angle brackets denote an ensemble average, and the correlation time τ_c for the motion can be determined with the help of experiments. There are many examples of exponentially decaying correlation functions. For instance, thermal motion of molecules in liquids was first treated in the classical BPP paper by Bloembergen. Spectral density calculations for liquids normally use a classical picture for the lattice. Quantum calculations of spectral densities are feasible for spin relaxation due to lattice vibrations or conduction electrons. Such calculations are, in general, impossible since the eigenstates of the lattice are often unknown. Molecular motions that are too fast ($\omega_0\tau_c \ll 1$) or too slow ($\omega_0\tau_c \gg 1$) with respect to the inverse of the Larmor frequency ω_0 are not amenable to nuclear spin-lattice relaxation (T_1) studies. Fortunately, measurements of spin-spin relaxation time (T_2) or spin-lattice relaxation time ($T_{1\rho}$) in the rotating frame can be used. Both T_1 and T_2 appear in the phenomenological Bloch equations, which describe the precession of nuclear magnetization in an external magnetic field. In NMR, the coupling between the lattice and the Zeeman reservoir of the nuclear spin system is magnetic in all cases except one. The exception is the quadrupole coupling between the nuclear quadrupole moment (for spin angular momentum $I > \frac{1}{2}$) and the lattice via an electric field gradient, which is electrical in nature. When this coupling exists, it is generally more efficient than any magnetic coupling. Relaxation of a quadrupolar nucleus of spin $I=1$ (i.e. ^2H) will be explicitly addressed. The deuteron has a small quadrupole moment with a coupling constant e^2qQ/b typically 150–250 kHz, large enough so that relaxation is dominated by the quadrupole interaction and small enough so that perturbation theory is applicable. In liquids, the couplings between nuclear spins are greatly reduced by rapid thermal motions of molecules. Since these couplings are weak and comparable to the coupling of the spins with the lattice, one can consider relaxation of individual spins or, at most, groups of spins inside a molecule. For deuterated molecules in liquids, the dipole-dipole coupling between deuterons is much weaker

than the quadrupole interaction. As a consequence, one can normally consider a collection of isolated deuteron spins in liquid samples.

Theory

Suppose that an assembly of N identical spin systems is considered. This allows a quantum statistical description of a spin system, for example the k th spin system in the ensemble. If the spin system is in a state with wavefunction or ket $|\psi_k\rangle$, the expectation value of a physical observable given by its operator Q is

$$\langle Q \rangle_k = \langle \psi_k | Q | \psi_k \rangle \quad [2]$$

NMR spectroscopy deals with the observation of macroscopic observables rather than states of individual spin systems. Thus, one needs to perform an average over the members of the ensemble:

$$\langle Q \rangle = \sum_{k=1}^N \langle Q \rangle_k / N \quad [3]$$

In general, the ket $|\psi_k\rangle$ is time dependent and may be expanded using a complete orthonormal basis set of m stationary kets $|\phi_\beta\rangle \equiv |\beta\rangle$:

$$|\psi_k\rangle = \sum_{\beta=1}^m C_\beta^k(t) |\beta\rangle \quad [4]$$

where the expansion coefficients C_β^k are time dependent. This leads to

$$\langle Q \rangle = \sum_{\alpha,\beta} \langle \beta | Q | \alpha \rangle \sigma_{\alpha\beta}(t) \quad [5]$$

where the matrix elements of a density operator σ are defined by

$$\sigma_{\alpha\beta} = \langle \alpha | \sigma | \beta \rangle = \overline{C_\alpha(t) C_\beta^*(t)} \quad [6]$$

and the bar denotes an ensemble average. Now the density operator is Hermitian and has real eigenvalues. In particular, its diagonal elements $\sigma_{\alpha\alpha}$ represent the probabilities of finding ket $|\alpha\rangle$ (or populations of $|\alpha\rangle$) in $|\psi\rangle$. The equation of motion for σ can easily be obtained from the Schrödinger equation for $|\psi\rangle$,

$$\frac{d}{dt} |\psi\rangle = -iH |\psi\rangle \quad [7]$$

where H is an appropriate spin Hamiltonian (in angular frequency units) for the spin system. The result is the Liouville-von Neumann equation for the time dependence of the density operator σ :

$$\frac{d\sigma}{dt} = -i[H, \sigma(t)] \quad [8]$$

A spin system with the Hamiltonian given by

$$H = H_0 + H'(t) \quad [9]$$

is now taken, where H_0 is the static Hamiltonian and $H'(t)$ represents time-dependent spin–lattice coupling. H' is a random function of time with a vanishing time average [i.e. $\overline{H'(t)} = 0$], and H_0 includes the Zeeman interactions, static averages of dipolar and quadrupole couplings, and time-dependent radiofrequency (RF) interactions. Writing σ and H' as $\tilde{\sigma}$ and $\tilde{H}'$ in the *interaction* representation and using second-order perturbation theory, the time evolution of the density operator can be shown to obey

$$\frac{d\tilde{\sigma}}{dt} = - \int_0^t dt' [\overline{\tilde{H}'(t) [\tilde{H}'(t-t'), (\tilde{\sigma}(t) - \sigma_{\text{eq}})]}] \quad [10]$$

where the bar is now used to indicate an average over all identical molecules in the sample. Using the eigenket basis of the static Hamiltonian H_0 , Redfield has obtained a set of linear differential equations:

$$\begin{aligned} \frac{d}{dt} \tilde{\sigma}_{\alpha\alpha'} &= \sum_{\beta\beta'} \exp[-i(\omega_{\alpha'\alpha} - \omega_{\beta'\beta})t] \\ &\times R_{\alpha\alpha'\beta\beta'} [\tilde{\sigma}_{\beta\beta'}(t) - \tilde{\sigma}_{\beta\beta'}(\infty)] \end{aligned} \quad [11]$$

where $\omega_{\alpha\beta} = \alpha - \beta$ ($\equiv E_\alpha - E_\beta$), $\tilde{\sigma}_{\beta\beta'}(\infty)$ corresponds to the matrix elements $\tilde{\sigma}_{\beta\beta'}$ at thermal equilibrium, and $\mathbf{R}$, the Redfield relaxation supermatrix, is given by

$$\begin{aligned} R_{\alpha\alpha'\beta\beta'} &= U_{\alpha\alpha'\beta\beta'} + U_{\beta'\beta\alpha\alpha'} \\ &- \delta_{\alpha'\beta'} \sum_{\gamma} U_{\gamma\gamma\beta\alpha} - \delta_{\alpha\beta} \sum_{\gamma} U_{\beta'\alpha'\gamma\gamma} \end{aligned}$$

This treatment is closely related to the relaxation theory of Wangsness and Bloch. The U functions are further simplified by examining, for example, $U_{\alpha\alpha'\beta\beta'}$,

$$\begin{aligned} U_{\alpha\alpha'\beta\beta'} &= \int_0^{\Delta t} d\tau \exp(-i\omega_{\alpha'\beta'}\tau) G_{\alpha\beta\alpha'\beta'}(\tau) \\ &\times \left[\frac{\exp\{i(\alpha - \beta - \alpha' + \beta')(\Delta t - \tau)\} - 1}{i(\alpha - \beta - \alpha' + \beta')\Delta t} \right] \end{aligned} \quad [12]$$

where $G_{\alpha\alpha'\beta\beta'}(\tau)$ denote time correlation functions of a stationary random function $H'(t)$, which is by definition independent of the origin of time, and

$$G_{\alpha\beta\alpha'\beta'}(\tau) = \overline{H_{\alpha'\beta'}^*(t) H_{\alpha\beta}(t + \tau)} \quad [13]$$

where $H_{\alpha\beta}(t) = \langle \alpha | H'(t) | \beta \rangle$. Note that the integrand is large only if $\tau \ll \tau_c$, the correlation time for $G_{\alpha\beta\alpha'\beta'}(\tau)$. Thus, the upper limit (Δt) of the integral can be set to

infinity. The bracket in the integrand is a constant ($\Delta t \gg \tau$) and equals 1. In this limit, $U_{\alpha\alpha'\beta\beta'}$ become the spectral densities $J_{\alpha\beta\alpha'\beta'}(\omega_{\beta'\alpha'})$ given by

$$J_{\alpha\beta\alpha'\beta'}(\omega_{\alpha'\beta'}) = \int_0^\infty \exp(-i\omega_{\alpha'\beta'}\tau) G_{\alpha\beta\alpha'\beta'}(\tau) d\tau \quad [14]$$

and the relaxation matrix elements are now given by

$$\begin{aligned} R_{\alpha\alpha'\beta\beta'} &= J_{\alpha\beta\alpha'\beta'}(\omega_{\alpha'\beta'}) + J_{\alpha\beta\alpha'\beta'}(\omega_{\alpha\beta}) \\ &- \delta_{\alpha'\beta'} \sum_{\gamma} J_{\gamma\beta\gamma\alpha}(\omega_{\gamma\alpha}) - \delta_{\alpha\beta} \sum_{\gamma} J_{\gamma\alpha'\gamma\beta'}(\omega_{\gamma\alpha'}) \end{aligned} \quad [15]$$

Because of the large heat capacity of the lattice relative to that of the nuclear spins, the lattice may be considered at all times to be in thermal equilibrium, while the time-varying spin states, in the absence of an RF field, evolve to thermal equilibrium because of the spin–lattice interactions. When the exponential argument $[(\omega_{\alpha'\alpha} - \omega_{\beta'\beta})$ in eqn [11]] is significantly larger than the spin relaxation rates, the exponential term oscillates rapidly in comparison with the slow variation in the density matrix due to relaxation. As a consequence, the impact of these terms becomes zero. The so-called secular approximation ($\omega_{\alpha'\alpha} = \omega_{\beta'\beta}$) effectively simplifies the equation of motion to

$$\frac{d}{dt} \tilde{\sigma}_{\alpha\alpha'} = \sum'_{\beta\beta'} R_{\alpha\alpha'\beta\beta'} [\tilde{\sigma}_{\beta\beta'}(t) - \tilde{\sigma}_{\beta\beta'}(\infty)] \quad [16]$$

where the prime on the summation indicates that only terms that satisfy $\omega_{\alpha'\alpha} = \omega_{\beta'\beta}$ are kept. Now the exponentials in front of those $R_{\alpha\alpha'\beta\beta'}$ terms in eqn [11] are clearly secular. These $R_{\alpha\alpha'\beta\beta'}$ parameters control the spin–lattice relaxation and are associated with the diagonal elements $\tilde{\sigma}_{\alpha\alpha}$, which specify the probabilities (P_α) that spin states $|\alpha\rangle$ are occupied. The exponentials in front of $R_{\alpha\beta\alpha\beta}$ are also secular. These $R_{\alpha\beta\alpha\beta}$ parameters control the spin–spin relaxation. When only spin–lattice relaxation is considered, the important Redfield terms in the eigenbase representation are limited to the following two types:

$$\begin{aligned} R_{\alpha\alpha\beta\beta} &= 2J_{\alpha\beta\alpha\beta}(\omega_{\alpha\beta}) - 2\delta_{\alpha\beta} \sum_{\gamma} J_{\gamma\beta\gamma\alpha}(\omega_{\gamma\beta}) \\ R_{\alpha\alpha\alpha\alpha} &= - \sum_{\gamma \neq \alpha} 2J_{\gamma\alpha\gamma\alpha}(\omega_{\gamma\alpha}) = - \sum_{\gamma \neq \alpha} R_{\gamma\gamma\alpha\alpha} \end{aligned} \quad [17]$$

Now $H'(t)$ in eqn [9] determines what is called the spin relaxation mechanism. As an example, the dipole–dipole Hamiltonian or quadrupolar Hamiltonian with an axially symmetric ($\eta=0$) electric field gradient tensor is given by

$$H'_\lambda(t) = \sum_{m_\lambda} A_{2,m_\lambda} \{ D_{m_\lambda,0}^2[\Omega(t)] - \overline{D_{m_\lambda,0}^2} \} \quad [18]$$

where the time dependence arises via Euler angles Ω in the Wigner rotation matrices $D_{m,\mu}^2(\Omega)$, and A_{2m_L} is defined by

$$A_{2,m_L} = C_{\lambda,\rho_{2,0}} T_{2,m_L}$$

with $C_{\lambda,\rho_{2,0}} = \sqrt{3/8}(e^2 q Q / \hbar)$ for the quadrupole ($I=1$) terms, and for the dipolar Hamiltonian this is $-\sqrt{3/8}(\mu_0 \gamma_i \gamma_j \hbar / \pi r_{ij}^3)$, where γ is the gyromagnetic ratio of a nuclear spin, r_{ij} is the internuclear distance between the spin pair, and μ_0 is the magnetic vacuum permeability. T_{2,m_L} , the spin operators in the laboratory frame, are given for a deuteron by

$$\begin{aligned} T_{2,0} &= \frac{1}{\sqrt{6}}(3I_z^2 - I^2) \\ T_{2,\pm 1} &= \mp \frac{1}{2}(I^\pm I_z + I_z I^\pm) \\ T_{2,\pm 2} &= \frac{1}{2}(I^\pm)^2 \end{aligned}$$

A similar set of equations can be written for the case of a pair of $I = \frac{1}{2}$ spins. When the cross-products between spin Hamiltonian matrix elements of different m_L values can be ignored (e.g. in liquids) where m_L is the projection index of a rank $L(=2)$ interaction Hamiltonian, the spectral densities of eqn [14] become

$$\begin{aligned} J_{\alpha\beta\alpha'\beta'}(\omega_{\alpha\beta}) &= \sum_{m_L} \langle \alpha | A_{2,m_L} | \beta \rangle \\ &\times \langle \alpha' | A_{2,m_L} | \beta' \rangle^* J_{m_L}(\omega_{\alpha\beta}) \end{aligned} \quad [19]$$

where

$$J_{m_L}(\omega) = \int_0^\infty G_{m_L}(\tau) \exp(-i\omega\tau) d\tau \quad [20]$$

with

$$\begin{aligned} G_{m_L}(\tau) &= \left\langle \left\{ D_{m_L,0}^2[\Omega(t)] - \overline{D_{m_L,0}^2} \right\} \right. \\ &\quad \left. \times \left\{ D_{m_L,0}^{2*}[\Omega(t-\tau)] - \overline{D_{m_L,0}^{2*}} \right\} \right\rangle \end{aligned} \quad [21]$$

It should be noted that the $J_{m_L}(\omega)$ are quantities that are obtained from experiments without reference to any molecular dynamics model. Now, eqn [11] can be transformed back to the Schrödinger representation:

$$\left| \frac{d}{dt} \sigma_{\alpha\alpha'}(t) = i[\sigma, H_0]_{\alpha\alpha'} + \sum_{\beta\beta'} R_{\alpha\alpha'\beta\beta'} [\sigma_{\beta\beta'}(t) - \sigma_{\beta\beta'}(\infty)] \right| \quad [22]$$

The first term on the right-hand side describes spin precessions and is only important for spin-spin relaxation. According to Redfield, the above equation is valid

provided that the relaxation elements are small in comparison to the inverse correlation time τ_c^{-1} of the thermal motion, i.e.

$$\frac{1}{R_{\alpha\alpha'\beta\beta'}} \gg \Delta t \gg \tau_c$$

where Δt represents the time interval over which the density matrix of the spin system has not appreciably changed. Different nuclear spin relaxation mechanisms (i.e. quadrupole, dipole-dipole, spin-rotation, chemical-shift anisotropy, and scalar spin-spin relaxation) are surveyed below. The list of relaxation mechanisms is by no means inclusive, but contains the most commonly discussed mechanisms.

Quadrupole Relaxation

Let us apply the Redfield theory to a deuteron with its quadrupole moment experiencing a fluctuating electric field gradient arising from anisotropic molecular motions in liquids. When the static average of quadrupole interaction is nonzero, i.e. $\overline{H_Q} \neq 0$, it can be included in the static Hamiltonian H_0 . The density operator matrix for a deuteron spin is of the dimension 3×3 and the corresponding Redfield relaxation supermatrix has the dimension $3^2 \times 3^2$. When only nuclear spin-lattice relaxation is considered, the spin precession term in eqn [22] is set to zero and the diagonal elements $\sigma_{\alpha\alpha}$ ($\alpha = 1, 2, 3$) satisfy

$$\frac{d}{dt} P_\alpha(t) = \sum_\beta R_{\alpha\beta} [P_\beta(t) - P_\beta(\infty)] \quad [23]$$

where $P_1 \equiv P_1$, $P_2 \equiv P_0$ and $P_3 \equiv P_{-1}$ are the populations in spin states $|1\rangle$, $|0\rangle$ and $|-1\rangle$, respectively (see **Figure 1**), and $R_{\alpha\beta} \equiv R_{\alpha\alpha\beta\beta}$ given in eqn [17]. $R_{\alpha\beta}$ represents the transition probability per second from the spin state β to the spin state α and $R_{\alpha\beta} = R_{\beta\alpha}$. Thus, nuclear spin-lattice relaxation involves transitions induced between nuclear states of different energies by the time-dependent part of quadrupolar interactions $H_Q(t) - \overline{H_Q}$. Solving eqn [23] in terms of linear combinations of the eigenstate populations P_α gives

$$\begin{aligned} &\begin{pmatrix} 1 & 0 & 0 \\ 0 & \exp(-t/T_{1Z}) & 0 \\ 0 & 0 & \exp(-t/T_{1Q}) \end{pmatrix} \\ &\times \begin{pmatrix} P_1(0) + P_0(0) + P_{-1}(0) \\ P_1(0) - P_{-1}(0) \\ -P_1(0) + 2P_0(0) - P_{-1}(0) \end{pmatrix} \end{aligned} \quad [24]$$

Figure 1 Energy level diagram for (right) a deuteron spin ($\eta=0$) and for (left) a pair of protons ($l=1$ triplet; $l=0$ is not shown) in an external magnetic field. $\omega_0/2\pi$ is the Larmor frequency.

where the deuteron spin-lattice relaxation times T_{1Z} and T_{1Q} for relaxation of the Zeeman and quadrupolar orders, respectively, are

$$T_{1Z}^{-1} = K_Q [J_1(\omega_0) + 4J_2(2\omega_0)] \quad [25]$$

$$T_{1Q}^{-1} = 3K_Q J_1(\omega_0) \quad [26]$$

where $K_Q = (3\pi^2/2)(e^2qQ/b)^2$. The asymmetry parameter η of the quadrupolar coupling is assumed to be zero here. T_{1Z} can be measured using an inversion-recovery pulse sequence, while T_{1Q} can be obtained using the Jeener-Broekaert pulse sequence $90_x^\circ - \tau - 45_y^\circ - t - 45_y^\circ$.

When considering spin-spin relaxation, it is necessary to examine the off-diagonal elements $\sigma_{\alpha\beta}$ of the density operator matrix and there are three independent spin-spin relaxation times (T_{2a} , T_{2b} , and T_{2D}):

$$\begin{aligned} T_{2a}^{-1} &= K_Q \left[\frac{3}{2}J_0(0) + \frac{5}{2}J_1(\omega_0) + J_2(2\omega_0) \right] \\ T_{2b}^{-1} &= K_Q \left[\frac{3}{2}J_0(0) + \frac{1}{2}J_1(\omega_0) + J_2(2\omega_0) \right] \\ T_{2D}^{-1} &= K_Q [J_1(\omega_0) + 2J_2(2\omega_0)] \end{aligned} \quad [27]$$

The quadrupolar (solid) echo pulse sequence ($90_x^\circ - \tau - 90_y^\circ$) allows measurement of the spin-spin relaxation

time T_{2a} . The double-quantum spin-spin relaxation rate T_{2D}^{-1} can be determined using a double quantum spin-echo pulse sequence $90^\circ - \tau - 90^\circ - t_1/2 - 180^\circ - t_1/2 - 90^\circ$. The first two 90° pulses create the double-quantum coherence, which is refocused by a 180° pulse, and the spin-echo is detected by the last monitoring 90° pulse.

Dipole-Dipole Relaxation

Treatment of spin-lattice relaxation of an isolated spin- $\frac{1}{2}$ pair by an intramolecular dipole-dipole interaction is identical to that for a spin-1 system (see Figure 1). Two like spin- $\frac{1}{2}$ nuclei separated by an internuclear distance r are considered. The longitudinal or Zeeman spin-lattice relaxation time T_{1Z} is given by eqn [25], but with K_Q replaced by a different multiplicative constant $K_D = \frac{3}{2}(\mu_0\gamma^2\hbar/4\pi r^3)^2$ which determines the dipolar coupling strength. In solids with isolated spin- $\frac{1}{2}$ pairs, the Jeener-Broekaert sequence can be used to determine the dipolar spin-lattice relaxation time T_{1D} which is the counterpart of T_{1Q} described above. Now T_{1Z} depends on the spectral density of the dipolar interaction fluctuations at the Larmor frequency and twice the Larmor frequency, whereas T_{1D} depends in addition on the spectral density of dipolar fluctuations in the low-frequency region around the line width of dipolar couplings. Thus T_{1D} can be quite sensitive to slow motions, which can significantly contribute to the spectral density at low frequencies. Similarly, the transverse or spin-spin relaxation rate for a spin- $\frac{1}{2}$ pair is, according to T_{2a}^{-1} in eqn [27], given by

$$T_2^{-1} = K_D \left[\frac{3}{2}J_0(0) + \frac{5}{2}J_1(\omega_0) + J_2(2\omega_0) \right] \quad [28]$$

The spin-lattice relaxation rate ($T_{1\rho}^{-1}$) in the rotating frame is given by

$$T_{1\rho}^{-1} = K_D \left[\frac{3}{2}J_0(2\omega_1) + \frac{5}{2}J_1(\omega_0) + J_2(2\omega_0) \right] \quad [29]$$

where ω_1/γ is the spin-locking field B_1 .

Now suppose the motional process (e.g. rotational Brownian motion in normal liquids) can be described by a single exponential correlation function of the form given in eqn [1]. The corresponding spectral density, which appears in the BPP theory, is a Lorentzian function:

$$J(\omega_0) = \frac{1}{5} \left(\frac{\tau_c}{1 + \omega_0^2\tau_c^2} \right) \quad [30]$$

where τ_c is a correlation time for the rotational motion. Hence,

$$T_1^{-1} = \frac{1}{5}K_D \left(\frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad [31]$$

$$T_2^{-1} = \frac{1}{5}K_D \left(\frac{3}{2}\tau_c + \left(\frac{5}{2} \right) \frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad [32]$$

In **Figure 2**, a sketch of these two equations as a function of τ_c is shown. As seen in this figure, $T_1 = T_2$ in the extreme narrowing limit ($\omega_0 \tau_c \ll 1$), which is observed in isotropic liquids. Note also that T_1^{-1} goes through a maximum at $\omega_0 \tau_c \sim 1$.

The above equations are developed for the rotational motion which modulates *intramolecular* dipole–dipole interactions in isotropic liquids. Translational motion can also cause spin relaxation by modulating *intermolecular* dipole–dipole interactions. Again for a pair of like spin- $\frac{1}{2}$ nuclei on two different molecules, the relaxation rate T_{1T}^{-1} due to translation involves different correlation times and somewhat different spectral densities:

$$T_{1T}^{-1} = \frac{9}{8}(\mu_0 \gamma^2 \hbar / 4\pi)^2 [J_1(\omega_0) + 4J_2(2\omega_0)] \quad [33]$$

This relaxation mechanism is important when ^1H NMR is used to study protonated samples and samples that contain paramagnetic impurities like oxygen. As the gyromagnetic ratio of an electron is about 1000 times greater than that of a proton, a small amount of paramagnetic impurity can drastically reduce the T_1 values in a sample.

For the case of an unlike spin- $\frac{1}{2}$ pair in a molecule (e.g. ^{13}C – ^1H), the Zeeman spin–lattice relaxation time for the resonant (I) spin depends on the spectral density at its Larmor frequency (ω_I), at the sum ($\omega_I + \omega_S$) and

difference ($\omega_I - \omega_S$) of the two Larmor frequencies for the spins I and S :

$$T_1^{-1} = \frac{1}{3}K'_D [J_0(\omega_I - \omega_S) + 3J_1(\omega_I) + 6J_2(\omega_I + \omega_S)] \quad [34]$$

where $K'_D = \frac{3}{2}(\mu_0 \gamma_I \gamma_S \hbar / 4\pi r^3)^2$.

Spin–Rotation Relaxation

A rotating molecule or a rotating group of atoms is a rotating charge system, thereby it can generate a magnetic field at the resonant nucleus. The fluctuating magnetic field depends on the magnitude and/or orientation of the angular momentum vector of the rotating molecule. Spin–rotation interactions can be an effective relaxation mechanism if the timescale of the fluctuating magnetic field at the nucleus is comparable to the inverse of the Larmor frequency. This is often encountered as the collisions among small molecules become infrequent. This mechanism is, therefore, important for gases, small molecules, and freely rotating groups ($-\text{CH}_3$, $-\text{CF}_3$). For molecules undergoing isotropic rotation in liquids, the longitudinal relaxation rate due to the spin–rotation interaction is

$$T_1^{-1} = \frac{2\pi kT}{\hbar^2} I_m C_{\text{eff}}^2 \tau_J \quad [35]$$

where k is the Boltzmann constant, T the absolute temperature, I_m the moment of inertia of the molecule, τ_J the angular momentum correlation time, and $C_{\text{eff}}^2 = \frac{1}{3}(C_{\parallel}^2 + 2C_{\perp}^2)$ with $C_{\parallel}$ and $C_{\perp}$ being the principal elements of the spin–rotation interaction tensor $\mathbf{C}$ parallel and perpendicular to the symmetry axis of the molecule, respectively. While the correlation time τ_c for molecular rotation decreases with increasing temperature, τ_J becomes longer. They are related by the simple relation:

$$\tau_c \tau_J = \frac{I_m}{6kT} \quad [36]$$

Hence it is a characteristic feature for the spin–rotation relaxation to show an opposite temperature dependence to that observed for the other relaxation mechanisms.

Chemical-Shift Anisotropy Relaxation

The magnetic field at a resonant nucleus depends on the applied B_0 field, as well as the screening of the applied field at the nucleus by the surrounding electrons. As the shielding (or chemical shift) tensor is anisotropic, its magnitude fluctuates with time due to modulations by molecular rotations. The fluctuating magnetic field at a nucleus from the chemical-shift anisotropy can cause spin relaxation. This relaxation mechanism depends on

Figure 2 Plot of the τ_c functions in eqn [31] (solid curve) and eqn [32] (dotted curve) as a function of the correlation time τ_c for $\omega_0/2\pi = 100$ MHz.

the square of the applied B_0 field and is therefore important at high fields. It also tends to dominate for nuclei exhibiting large chemical-shift ranges. For molecules with axial symmetry, one can obtain:

$$T_1^{-1} = \frac{2}{15} \gamma^2 B_0^2 (\sigma_{\parallel} - \sigma_{\perp})^2 \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad [37]$$

$$T_2^{-1} = \frac{2}{15} \gamma^2 B_0^2 (\sigma_{\parallel} - \sigma_{\perp})^2 \left[\frac{2\tau_c}{3} + \left(\frac{1}{2} \right) \frac{\tau_c}{1 + \omega^2 \tau_c^2} \right] \quad [38]$$

where $\sigma_{\parallel}$ and $\sigma_{\perp}$ are the principal components of the chemical-shift tensor parallel and perpendicular to the symmetry axis of the molecule, respectively. In contrast with the dipole-dipole relaxation, the longitudinal and transverse rates do not tend to the same value in the limit of short τ_c , as seen in the above equations.

Scalar Relaxation

For spin-spin (scalar) coupling between spins I and S , where $I = \frac{1}{2}$ and $S \geq \frac{1}{2}$, the interaction Hamiltonian involves the scalar coupling tensor $\mathbf{J}$. The scalar relaxation of the nucleus I can arise from either a time-dependent $\mathbf{S}$ or a time-dependent $\mathbf{J}$ ('first kind'). If the relaxation time ($T_1(S)$) of the nucleus S is short compared with $1/J$, where J is the scalar coupling constant, the nucleus I sees the average of the spin-spin interaction and does not show the expected multiplet, but a single line. The scalar relaxation correlation time τ_s is then equal to $T_1(S)$, and the scalar spin-spin contributions to the longitudinal and transverse relaxation times of the I nucleus are given by

$$T_1^{-1} = \frac{8\pi^2 J^2}{3} S(S+1) \frac{\tau_s}{1 + (\omega_I - \omega_S)^2 \tau_s^2} \quad [39]$$

$$T_2^{-1} = \frac{4\pi^2 J^2}{3} S(S+1) \left[\tau_s + \frac{\tau_s}{1 + (\omega_I - \omega_S)^2 \tau_s^2} \right] \quad [40]$$

Scalar relaxation of the first kind involves collapse of spin multiplets. When $T_1(S)$ is primarily due to the quadrupole relaxation for $S > \frac{1}{2}$, this is often referred to as scalar coupling of the second kind. In the above equations, the denominators involving $\omega_I - \omega_S$ become very large when the Larmor frequencies ω_I and ω_S are very different. In this case, the scalar relaxation becomes unimportant for T_1 , but still exists for T_2 due to the frequency-independent term in eqn [40].

Spectral Density of Motion

As mentioned above, the evaluation of correlation functions or spectral densities is a daunting task for any

relaxation theory. To further complicate the matter, different motional (or relaxation) processes can simultaneously occur in the material being studied by nuclear spin relaxation. However, the observed relaxation rate can often be given by

$$T_1^{-1} = T_{1a}^{-1} + T_{1b}^{-1} + T_{1c}^{-1} + \dots \quad [41]$$

provided that different relaxation mechanisms labelled by the subscripts a, b, c occur at very different timescales. Otherwise, possible couplings between these processes may also exist and their contributions to relaxation must be properly treated.

In the above discussion of the quadrupole and dipole-dipole relaxation, the relaxation rates are written in terms of spectral densities for general applications. As an example, the reorientation correlation functions ($g_{mn}(t)$) for molecules rotating in an anisotropic medium are calculated using a rotational diffusion model. The rotational diffusion equation, which involves a rotational diffusion operator (Γ) and also contains the pseudopotential for reorienting molecules, must first be solved to get the conditional probability that a molecule has a certain orientation at time t given it has a different orientation at time $t=0$. This, together with the equilibrium probability for finding the molecule with a certain orientation, is required to work out $g_{mn}(\tau)$. In general, the orientational correlation functions can be written as a sum of decaying exponentials:

$$g_{mn}(t) = \sum_K (\beta_{mn}^2)_K \exp[(\alpha_{mn}^2)_K t] \quad [42]$$

where m and n represent the projection indices of a rank 2 tensor in the laboratory and molecular frames, respectively; $(\alpha_{mn}^2)_K/\rho$, the decay constants, are the eigenvalues of the rotational diffusion Γ matrix and $(\beta_{mn}^2)_K$, the relative weights of the exponentials, are the corresponding eigenvectors. In this model, the decay constants contain the model parameters $D_{\parallel}$ and $D_{\perp}$ specifying rotational diffusions of the molecule about its long axis and perpendicular to the long axis. The spectral densities for a deuteron residing on the rigid part of a uniaxial molecule are the Fourier transform of the orientational correlation functions ($m=0, 1$, or 2) to give

$$J_m(m\omega) = \sum_n \left[d_{n,0}^2(\beta_{M,Q}) \right]^2 \sum_K \frac{(\beta_{mn}^2)_K^2 (\alpha_{mn}^2)_K^2}{(\alpha_{mn}^2)_K^2 + m^2 \omega^2} \quad [43]$$

These can now be substituted into eqns [25–27] to obtain deuteron relaxation rates.

By fitting the experimental spectral densities with the predictions from a certain motional model, its model parameters can then be derived. However, the derived motional parameters are model dependent. It is a price one normally has to pay when using NMR relaxation

rates. Justification of NMR model parameters may be obtained by comparing them with those observed by other spectroscopic techniques.

T_2	transverse relaxation time
γ	gyromagnetic ratio
μ_0	magnetic field constant

Purpose and Classification of NMR Relaxometers

Nuclear magnetic relaxation, that is, thermal equilibration of the spin systems with respect to longitudinal or transverse magnetization components, multiple-quantum spin coherences and longitudinal dipolar, quadrupolar or scalar order, comprises a vast variety of different experimental protocols and phenomena. In a typical relaxation experiment, one first produces a nonequilibrium population of the spin states, often combined with spin coherences. It is then a matter of the fluctuations of the spin couplings to induce spin transitions towards thermal equilibrium. ‘Equilibrium’ means (i) populations following Boltzmann’s distribution, and (ii) completely vanishing spin coherences. Consequently there are three elements inherent in a typical relaxation experiment: *Preparation* of a nonequilibrium state of the spin systems; the variable *evolution* interval allowing for the induction of spin transitions; and the *detection* of the populations, longitudinal order, or coherences after the evolution interval. The time constants with which the ‘observable’ approaches equilibrium during the evolution interval are the relaxation times, such as the spin–lattice relaxation time T_1 , the transverse relaxation time T_2 , the rotating-frame relaxation time $T_{1\rho}$, the dipolar-order relaxation

time T_d , and so on. In the following we will focus on T_1 in particular.

The spin–lattice relaxation rate of dipolar coupled homonuclear two-spin I systems, for instance, is given by

$$\frac{1}{T_1} = \left(\frac{\mu_0}{4\pi}\right)^2 \frac{3}{2} \gamma^4 \hbar^2 I(I+1) [J^{(1)}(\omega) + J^{(2)}(2\omega)] \quad [1]$$

where μ_0 is the magnetic field constant, γ is the gyro-magnetic ratio, and $J^{(i)}(\omega)$ is the intensity function of the Larmor frequency, $\omega = \gamma B_0$, depending on the flux density of the external magnetic field, B_0 . The intensity function is given as the Fourier transform of the dipolar autocorrelation function $G_i(\tau)$,

$$J^{(i)}(\omega) = \int_{-\infty}^{\infty} G_i(\tau) \exp(-i\omega\tau) d\tau \quad [2]$$

The dipolar autocorrelation function is defined by

$$G_i(\tau) = \langle F^{(i)}(0) F^{(-i)}(\tau) \rangle \quad [3]$$

where

$$F^{(1)} = \frac{1}{r^3} \sin \vartheta \cos \vartheta \exp(-i\varphi),$$

$$F^{(2)} = \frac{1}{r^3} \sin^2 \vartheta \exp(-2i\varphi) \quad [4]$$

The polar coordinates r , ϑ , φ define the internuclear vector of the spin system. That is, any molecular motion affecting these coordinates leads to fluctuations of the functions $F^{(i)}$, so that the spin–lattice relaxation rate (eqn [1]) directly reflects these motions via the intensity and autocorrelation functions. The prominent goal of NMR relaxometry, hence, is to monitor the features of molecular dynamics. This is best done by recording the frequency dependence of spin–lattice relaxation.

Variation of the Larmor frequency means variation of the external flux density B_0 . The range within which one can do that using conventional NMR spectrometers is very limited. The reason is that the flux density has a fixed value given by the magnet in use. Typical values range from 1 to 20 T. The radio frequency (RF) part of conventional NMR spectrometers is tuned to resonance in the particular flux density provided by the magnet.

That is, there is no reasonable way to study frequency dependences using spectrometers with fixed flux densities, because the signal-to-noise ratio, $S/N \propto B_0^{3/2}$, and the RF bandwidth deteriorates the lower the flux density and the frequency become.

The solution of the problem is field-cycling NMR relaxometry. The essence of this technique is that the magnetic flux density relevant for relaxation is different from that during signal detection. The 'relaxation field' may be varied over several orders of magnitude while the 'detection field' is kept fixed at the highest possible value. That is, the RF console is tuned to this particular detection field. The design of a field-cycling relaxometer thus implies the possibility to switch the flux density rapidly and precisely between different levels with very good stability. A typical field cycle is shown in **Figure 1**.

Field-Cycling (FC) NMR Relaxometry

Principle

A typical field cycle consists of a preparation interval, an evolution interval and a detection interval. In the preparation interval the magnetic flux density, B_P , is chosen as high as technically possible. The purpose is to polarize the sample so that the magnetization becomes as large as feasible.

A nonequilibrium state is then produced by switching the magnetic field to another level, namely to that of the evolution interval, $B_E \neq B_P$. If the magnetic field is switched fast enough, so that the magnetization cannot follow the instantaneous equilibrium value given by Curie's law, we have a nonequilibrium situation at the beginning of the evolution interval. That is, the magnetization starts to relax towards the equilibrium value corresponding to the field level of the evolution interval.

The relaxation curve is then probed point-by-point by switching the field up to the detection field level and by acquiring the NMR signal using an RF pulse or an echo RF pulse sequence. The detection field is chosen as high as possible, and is the same for all experiments. This is the field to which the RF console is tuned. The amplitude of the NMR signal represents the magnetization at the end of the evolution interval, in which relaxation takes place. Thus varying the evolution interval permits one to record the whole relaxation curve to which the spin-lattice relaxation time can be fitted. Assuming monoexponential relaxation and neglecting losses during the switching intervals, the detected magnetization is given by

$$M(\tau) = M_E + [M_P - M_E] \exp[-\tau/T_1(B_E)] \quad [5]$$

where M_E and M_P are the Curie magnetizations corresponding to the magnetic flux density in the evolution and

Figure 1 Typical cycle of a field-cycling NMR relaxometer serving for spin-lattice relaxation experiments: (a) External magnetic flux density $B_0 = B_0(t)$, (b) longitudinal magnetization $M = M(t)$ in the sample, (c) RF pulse with free-induction decay (FID) during the detection period. Note that the field level in the (short) detection period is much higher than in the (long) polarization interval. This ensures equivalent heat production in both intervals.

polarization intervals, respectively. Incrementing the evolution field level, B_E , in subsequent experiments permits one to measure such relaxation curves at field levels not accessible to conventional NMR. That is, the whole frequency dispersion of spin–lattice relaxation can be probed with a relaxometer tuned to a fixed resonance frequency. This implies that the signal-to-noise ratio remains the same for all Larmor frequencies.

Requirements and Limitations

Signal-to-noise ratio

According to Curie's law, the magnetization reached in the polarization field, B_P is $M_P \propto B_P$. The induction signal increases proportionally to the detection field, B_D , whereas noise is proportional to the square root of the carrier frequency, i.e. the square root of the detection field. The signal-to-noise ratio is thus determined by

$$S/N \propto B_D^{1/2} M(\tau) \quad [6]$$

The magnetization at the end of the evolution interval obeys

$$M(\tau) \geq B_P \exp[-\tau/T_1(B_E)] \quad [7]$$

so that the signal-to-noise ratio is limited by

$$S/N \propto B_D^{1/2} B_P \exp[-\tau/T_1(B_E)] \quad [8]$$

For optimum signal-to-noise ratio, this suggests field levels B_D and B_P as high as technically feasible.

Feasibility of phase-sensitive detection

An insufficient signal-to-noise ratio, as is likely with deuteron relaxation or with very dilute systems and small samples, can be improved with signal accumulation. This, however, requires a detection field stability permitting phase-sensitive detection. That is, after having switched the field up to the detection level, resonance must be reproducibly reached in all cycles of the experiment with an accuracy of 10^{-5} before signal acquisition. This is a rather demanding condition requiring a technical solution like the battery-driven power supply described below. By contrast, the accuracy of the polarization and evolution levels is much less critical. A few percent may be acceptable.

Thermal stability

The *polarization field*, B_P , is applied as long as needed for reaching thermal equilibrium, typically a period $t_P \approx 5 \times T_1(B_P)$. The *detection field*, B_D , is applied only in the very short interval t_D needed for acquiring the free-induction decay. That is,

$$t_P \gg t_D \quad [9]$$

Apart from a few superconducting versions reported in the literature, the magnet coils of field-cycling relaxometers are resistive, so that Joule's heat produced in the course of a field cycle affects the thermal stability of the system. If the magnet coil gets unduly warm during the polarization interval, thermal drifts of the field levels are unavoidable. Actually, the cooling properties of the magnet coil form a crucial factor limiting the applications. Considering the inequality given in eqn [9] it becomes obvious that it is more favourable to restrict the polarization field to a level still compatible with thermal stability, whereas the detection field should be as high as the magnet power supply permits. This is the reason why the field levels in the scheme shown in **Figure 1** are chosen in such a way that $B_D \gg B_P$.

Accuracy of the evolution field level

On a logarithmic field or frequency scale covering several orders of magnitude, an accuracy of better than 10% may be adequate. However, at low magnetic fields, relaxation times less than a millisecond may occur. That is, a stability of the evolution field level of less than 10% must be reached in a ring-down time of less than 1 ms after switching. The evolution field level must begin with a sharp edge in the time dependence of the magnetic flux density. This is another demanding specification which requires special current control measures (see the design described below). It is also an essential condition to check the switch interval from the polarization level to that of the evolution field with the aid of a suitable Hall probe and a fast high-resolution (e.g. 500 kHz/16 bit) analogue-to-digital converter (**Figure 2**).

Influence of the switching times

Provided that the time dependence of the magnetic flux density (see **Figure 1**) is reproducible in an experiment for a given evolution flux density, there is no influence on the measured spin–lattice relaxation time even when the switching intervals are comparable with the low-field relaxation times. However, the dynamic range of the magnetization variation in a relaxation experiment is reached only in full if the switching intervals are much shorter than the low-field relaxation times. That is, the best measuring accuracy is achieved if the relaxation losses during the switching intervals are negligible.

Lower limit of the evolution field

When the evolution field approaches the earth field, i.e. the field when the magnet is switched off, a compensation of this zero-field with the aid of correction coils becomes necessary. In this way, flux densities less than 5×10^{-5} T can reliably be reached. Another limit is due to the local field within the sample. The local field arises because of secular spin interactions. It cannot therefore be compensated by external correction coils. If the local field exceeds the external evolution field, two situations can

Figure 2 Precision of the initial stabilization of the evolution field. The plot represents the voltage transient recorded with a Hall probe ($6 \mu\text{T/mV}$) and a 16 bit analogue-to-digital converter. The field level corresponds to a proton Larmor frequency of 3.5 kHz. The field-cycling relaxometer is described below. This plot demonstrates that the evolution field can be stabilized within ± 1 digital unit in a ring-down time less than 1 ms.

arise. Firstly, the local field is approached by adiabatically switching off the polarization field. That is, the local magnetization vectors follow the instantaneous field direction which is finally given by the local field. In this case, dipolar or, in the case of quadrupole nuclei, quadrupolar order is produced. The relaxation time measured under such circumstances is the dipolar-order spin-lattice relaxation time. In the opposite case, the polarization field is switched off nonadiabatically so that the magnetization partly becomes transverse to the local field. This is the situation of the so-called zero-field NMR spectroscopy probing the evolution of spin coherences in the local field.

Field homogeneity

Fast field switching stipulates small magnet coils so that the field energy to be varied in a cyclic way is low. On the other hand, the field homogeneity of small magnets tends to be poor. For field-cycling relaxometry the condition is that the homogeneity within the sample should correspond to the stability (or reproducibility) of the detection field. That is, if the detection field can be reproduced with an accuracy of 10^{-5} , the field homogeneity in the sample need not to be better than 10^{-5} and using suitable magnet designs this can be achieved easily.

Crucial Specifications of Field-Cycling NMR Relaxometers

From the above outline of the factors limiting field-cycling NMR relaxometry, it becomes obvious that the

following specifications of a relaxometer are most crucial. (a) The polarization and detection fields should each be as high as compatible with the thermal stability of the magnet coil. This normally means that the detection field is much higher than the polarization field. (b) The evolution field must achieve stability within a few percent after a stabilization time of less than the shortest relaxation time to be measured. The total field switching intervals should preferably be shorter than the typical relaxation times of interest. (c) The detection field should be reproducible within 10^{-5} after a stabilization period of much less than the high-field relaxation time. This is the condition permitting phase-sensitive detection and, hence, automatic signal accumulation. (d) The field homogeneity in the sample should correspond to the reproducibility of the detection field, i.e. a relative field variation of less than about 10^{-5} .

Typical Setup of a Field-Cycling Relaxometer

Historically the first field-cycling instruments consisted of two magnets of varying flux densities. The sample was 'shuttled' between a resonant magnet and a magnet producing the variable evolution field. With modern relaxometers the field is varied much faster by controlling the current through the magnet coil electronically. This, of course, stipulates that the use of iron magnets is excluded. The magnets in use are resistive or even superconducting magnet coils with solenoid-like geometries.

Figure 4 Cross section of an easy-to-make and efficiently cooled field-cycling magnet. The solid vertical lines represent the six double-layers of windings of the magnet. The cooling medium is pressed through between these double layers.

Magnet Power Supply System

The magnet power supply is the most crucial part of a field-cycling relaxometer. It is a complicated system of commercial laboratory power supplies and certain measures for switching between different power supplies are optimized for different current ranges, and for connecting driver high-voltage capacitors to the magnet current circuit. The polarization and evolution fields above 4.2 mT are produced by a parallel combination of four modules of Kepco ATE 75–15 M. The maximum current in these intervals is 60 A. The resolution of evolution fields below 4.2 mT is improved by using a special low-current power supply (<800 mA) temporarily replacing the Kepco system.

The detection field is most demanding with respect to strength, stability and reproducibility. A series of 13 ordinary 12 V car batteries turned out to be best in these regards. In this way an extremely stable and reproducible current of about 300 A can be generated easily.

The transitions from high to low and from low to high magnetic fields are accelerated with the aid of a capacitor precharged to a voltage of 600 V. The polarity by which this driver capacitor is connected to the magnet current circuit depends on the direction of the transition.

For security, the system is surveyed by a unit checking the most important instrument parameters such as the cooling-oil temperature and pressure, and the storage capacitor voltage. In case the parameters deviate from the set point adjustment, the complete high-power part of the relaxometer is switched off within milliseconds.

In passive operation the time constant of the magnet coil is given by

$$\tau_m = \frac{L}{R} \quad [10]$$

where L and R are the inductance and the resistance of the coil, respectively. Employing semiconductor power switches as mentioned before permits one to actively control the field transition intervals. The following measures are in use.

- Reducing the flux density can be accelerated by dissipating the field energy in an ohmic damping resistor, R_d , connected to the magnet in series during the switching-down process. The magnet current then obeys the differential equation

$$-L \frac{dI}{dt} = I(R + R_d) - U_0 \quad [11]$$

where U_0 is the voltage induced by the current variation in the magnet coil. With the initial condition $I(0) = I_{\max} = U_0/R$ the solution becomes

$$I_d(t) = \frac{U_0}{R + R_d} + \left[\frac{U_0}{R} - \frac{U_0}{R + R_d} \right] \exp(-t/\tau_d) \quad [12]$$

with the new time constant

$$\tau_d = \frac{L}{R + R_d} \quad [13]$$

- The damping resistors can be efficiently supplemented by voltage suppressor diodes which cut off all voltages above a certain nominal value. The field energy is then dissipated in the diodes as well.
- The third possibility is to transfer the field energy temporarily to a capacitor. With opposite polarity, such a capacitor can be used to drive the field up as mentioned before. The principle is illustrated in **Figure 5**. The switches are single IGBT modules (Semikron SKM 400 GA) with maximum currents of 400 A at 1200 V. The switching rate can be changed by altering the gate resistor R_G . Induction-voltage peaks due to fast switching can be reduced by increasing R_G . The IGBT switches are controlled by a Semikron SKHI 20 module, which galvanically separates the input TTL signal from the gate. Additionally it contains a small surveillance unit for the IGBT (overvoltage and overtemperature protection), which feeds an error signal back to the Control Logic so that the cycle is immediately stopped in the fault case. During the *polarization period* the switch S_1 (IGBT 1) is closed, and G_1 drives the magnet current. Simultaneously the capacitor C is precharged to about 600 V. In the

Figure 5 Simplified scheme of the magnet current switching circuit for field-cycling purposes.

Table 1 Field values of the home-built relaxometer, expressed by the current and the Larmor frequencies of protons and deuterons

Field	Current (A)	$\nu_L(^1\text{H})$ (Hz)	$\nu_L(^2\text{H})$ (Hz)	Rel. deviation
Polarization	55	12.4×10^6	1.904×10^6	2×10^{-4}
Evolution (max.)	28.8	6.51×10^6	1.0×10^6	3×10^{-4}
Evolution (min.)	0.009	2.0×10^3	300	0.2^b
Detection ^a	267–273	$60\text{--}61.5 (\times 10^6)$	$9.2\text{--}9.5 (\times 10^6)$	1.5×10^{-5}

switching interval *polarization field* $\rightarrow$ *evolution field*, the digital-to-analogue converter defines a new set value for G_1 . The switch S_1 opens, and the network operates as a series resonance circuit. That is, the magnet energy is transferred to the capacitor. After the desired evolution field level has been reached, the switch S_1 closes again. In the *evolution interval*, either G_1 or G_2 controls the magnet current depending on the adjusted field level. The two alternate current amplifiers are used in order to improve the field resolution, limited by that of the 12 bit digital-to-analogue converter. In the switching interval *evolution field* $\rightarrow$ *detection field*, the switch S_2 is closed, and the precharged capacitor provides the peak power for driving the current up to the detection field level. S_3 then closes after a 1 ms delay. When the level of the detection field is reached, S_2 opens and the batteries supply a current of 300 A required for the detection field. Finally, in the *switching-off interval*, the switch S_1 opens, and the magnet energy is transferred to the capacitor again. When the current has decayed to zero, S_1 is closed. Before starting a new polarization/evolution/detection field cycle, a settling time of 2 to 3 s is allowed.

The Probehead

As the bore of field-cycling magnets are kept as small as possible, extremely compact designs of the RF probehead are unavoidable. Typical diameters range between 20 and 30 mm. All electrically conducting parts must be thoroughly slit in order to prevent the induction of eddy currents during the field cycle. The materials and the dimensions must be chosen in a way that the ohmic resistance is as high as possible. On the other hand, one must keep in mind that every slit works like an antenna, which might pick up undesired RF from other sources. Multiple layer shielding with interdigitated slits turn out to be best.

Figure 6 schematically illustrates the ‘heart’ of the probe, the sample compartment with the RF coil and the temperature sensor. It is arranged closely below the tune and match capacitors, and is surrounded by the RF shielding. The outer diameter is 23 mm, the length of the sample coil 17 mm, with a maximal diameter of 12 mm for the sample containers. The coil is tuned either for proton or for deuteron resonance. That is, a 5 turn coil for 62 MHz or a 70 turn coil for 9.5 MHz, respectively. A glass tube supplies the air stream for heating or cooling

Figure 6 Cross section through a probehead for field-cycling NMR relaxometry.

of the sample. The temperature is controlled using a Pt100 resistor with an accuracy of $\pm 1^\circ\text{C}$.

General Specifications

The total transition and ring-down time from the polarization field to a value of the evolution field, stable within $\pm 10\%$, is less than 3 ms at all evolution field levels. Resonance in the detection field is reached within $\pm 10^{-5}$, in a transition time of 2.5 ms. The field switching rates involved are 750 T s^{-1} . Typical field values are listed in **Table 1**. NMR relaxometers are now commercially available with compact design, digital NMR consoles, multi-nuclear operation, and efficient and accurate temperature control, allowing measurements of relaxation times ranging from several seconds to fractions of milliseconds.

Typical Spin-Lattice Relaxation Dispersion Curves

Field-cycling NMR relaxometry is a versatile and powerful method for investigating molecular dynamics over a large range of timescales. It has been applied to manifold materials which show broad distributions of molecular motions, for example proteins, liquid crystals, synthetic polymers, and liquids confined in porous

Figure 7 Typical ^1H and ^2H spin-lattice relaxation curves. The power laws in (a) are discussed in Kimmich, Fatkullin, Weber and Stapf (1994) (see Further reading). The solid lines in (b) correspond to a fit of 'reorientations mediated by translational displacements (RMTD) model described in Kimmich (1997) (see Further reading).

materials. **Figure 7a** represents an example for the investigation of polymer dynamics. The T_1 -dispersion curve in the double-logarithmic scale shows the typical slopes observed in polyethylene oxide melts above the critical molecular mass $\propto \nu^{0.5}$ and $\propto \nu^{0.25}$. The data can be explained by the renormalized Rouse theory. **Figure 7b** shows the ^2H -dispersion of D_2O in gelatine. Using deuterated water helps to clarify the mechanisms of water relaxation in biological tissue.

Introduction

The first observation of nuclear magnetic resonance (NMR) in bulk phases was published in 1946, and soon a number of instruments were constructed across the world. The realization that NMR spectroscopy would be useful for chemical characterization came with the discovery of the NMR chemical shift in 1951, and this led to the introduction of commercial spectrometers. By the end of the 1950s, a considerable number of publications on the application of NMR to chemical structuring and analysis problems had appeared, and then during the 1960s and later, it became clear that NMR could provide useful information about biological systems also. Since then, the applications and the consequential instrument developments have diversified, and now NMR spectroscopy is one of the most widely used techniques in chemical and biological analyses. The very high specificity, the exploratory nature of the technique, the lack of need to preselect analytes, and the nondestructive nature have made it very useful despite its lower sensitivity compared to some spectroscopic methods (*see* Magnetic Resonance, Historical Perspective).

The most commonly studied nuclide, certainly in chemical and biological applications, is that of the hydrogen atom, the proton, designated ^1H . This gives rise in isotropic solutions to sharp NMR peaks and has the highest sensitivity of any of the naturally occurring, nonradioactive isotopes (only the radioactive tritium nucleus ^3H is more sensitive). Many other nuclei have been widely studied using NMR spectroscopy, and these form the basis for many articles in this encyclopedia. For chemical studies, ^1H , ^{13}C , ^{15}N , and ^{19}F are the most commonly used nuclides, whereas for biochemical

studies, ^1H , ^{13}C , and ^{31}P probably are most common. For inorganic chemistry studies, most nuclei in the periodic table have at least one isotope that can give rise to NMR spectra, although often the properties will be unfavorable, giving very broad lines, having low natural abundance, having low inherent sensitivity, or indeed all three.

A general description is given here of the way in which a modern NMR spectrometer operates. The various components that go into the making of a complete system and their particular roles are also described. A block diagram of the components of a high-resolution NMR spectrometer is given in **Figure 1**.

Components and Principles of Operation of NMR Spectrometers

Continuous-Wave (CW) and Fourier Transform (FT) Operation

For many years, all commercial NMR spectrometers operated in continuous-wave mode. This type of operation required a sweep of the NMR frequency or the magnetic field over a fixed range to bring each nucleus into resonance one at a time. These scans for ^1H NMR spectroscopy would take typically 500 s to avoid signal distortion. This became a very inefficient process because most NMR spectra consist of a few sharp peaks interspersed with long regions of noise. A fundamental paper by Ernst and Anderson in 1966 pointed out the favorable gain in efficiency, which could be obtained by simultaneously detecting all signals. This is achieved by the application of a short intense pulse of radiofrequency (RF) radiation to excite the nuclei followed by the detection of the induced magnetization in the detector coil as the nuclei relax. The decaying, time-dependent signal, known as a free induction decay (FID), is then converted into the usual frequency domain spectrum by Fourier transformation (FT) (*see* Fourier Transformation and Sampling Theory; NMR Principles). For speed of implementation, in NMR computers the number of data points should be a power of 2, typically perhaps 16K points for modest spectral widths and up to 128K or even 256K points for wide spectral widths on high-field spectrometers (1K is 1024 or 2^{10} points). Acquisition of a ^1H FID requires typically a few seconds and opens up the possibility of adding together multiple FID scans to improve the signal-to-noise ratio (S/N), since for perfectly registered spectra, the signals will co-add but the noise will only increase in proportion to the square root of the number of scans. Therefore, the gain in

Figure 1 A block diagram of the principal components of a modern NMR spectrometer.

S/N is proportional to the square root of the number of scans. The first commercial FT-NMR spectrometers became available around 1970, and this, for the first time, really made routine the efficient and feasible acquisition of NMR spectra of less-sensitive or less-abundant nuclei such as ^{13}C .

The Magnet

The most fundamental component of an NMR spectrometer is the magnet. Originally, this would have been a permanent magnet or an electromagnet, and these

provided the usual configurations for field strengths up to 1.41 T (the unit of magnetic flux density is the Tesla (T) equivalent to 10 000 G), corresponding to a ^1H observation frequency of 60 MHz. Because the sensitivity of the NMR experiment is proportional to about the $3/2$ power of the field strength, denoted B_0 , there has been a drive to obtain higher and higher magnetic fields. This led the commercial NMR manufacturers to develop electromagnets that took the highest field strengths to 2.35 T, that is, 100 MHz for ^1H NMR observation. Materials suitable for electromagnets have maximum saturation field strengths at about this value, and the

quantity of electricity and the consequential water cooling required is a considerable running expense. Because of the continued need for even higher field strengths, NMR manufacturers have collaborated closely with magnet developers to produce high-resolution magnets based on superconducting solenoids. The magnetic field is generated by a current circulating in a coil of superconducting wire immersed in a cryostat filled with liquid helium at 4.2 K. This bath is shielded from ambient temperature by layers of vacuum and a jacket of liquid nitrogen at 77 K, which is usually topped up at a weekly interval. A liquid helium refill is carried out at approximately 3-month intervals, depending on the age and field strength of the magnet. The initial development of superconducting magnets around the early 1970s was at 5.17 T corresponding to 220 MHz for ^1H observation. At regular intervals, the available field strength gradually increased along with the emergence of wider bore magnets enabling the incorporation of larger samples. Thus, a 270 MHz spectrometer was produced along with a wide-bore 180 MHz machine and then the field was increased to allow ^1H observation at 360, 400, 500, 600, 700, 750, 800, and 900 MHz. The present limit of any commercial machine yet delivered to a customer is at 950 MHz (2008), although higher magnetic field spectrometers have been generated in specialist magnet laboratories. The development of the very high field magnets has required new technology in which part of the liquid helium bath is kept at about 2 K by an adiabatic cooling unit thereby allowing higher current to be used in the coils. This approach should lead to the availability of even higher field strengths in the near future. A photograph of a superconducting magnet designed to give a field of 18.8 T and ^1H NMR spectra at 800 MHz is shown in **Figure 2**, indicating the size that such magnets have reached. Nowadays, apart from very basic routine low-field spectrometers used, for example, for monitoring chemical reactions, all NMR spectrometers are based on superconducting magnets.

Sample Handling

High-resolution NMR spectra are usually measured in the solution state in glass tubes of standard external diameters, 5 mm being the most common, but larger ones (10 mm) are used where improved sensitivity is required and sample is not limited. Also, a range of narrow and specially designed tubes is available for limited sample studies including 4, 3, 1.5 mm diameter, and even smaller specially shaped cavities such as capillaries or spherical bulbs, plus tubes containing limited volume cavities where the glass has a magnetic susceptibility tailored to be the same as that of a specific NMR solvent such as D_2O .

Figure 2 A superconducting NMR magnet operating at 18.8 T for ^1H NMR observation at 800 MHz, demonstrating the size of these state-of-the-art magnets. This instrument is installed at Imperial College London. The magnet is placed in a pit approximately 1 m deep since it requires a ceiling clearance height of >5 m.

In analytical laboratories where large numbers of samples have to be processed, automatic sample changers now can play a large part in improving efficient use of the magnet time. These devices allow the measurement of up to about 120 samples in an unattended fashion with the insertion and ejection of samples from the magnet under computer control. Automatic lock detection and optimization, sample spinning, NMR receiver gain, and shimming (see the following text) are also standard, and even automatic frequency tuning and matching and pulse length calibration (see the following text) are possible. The data are acquired automatically and can be plotted and stored on backing devices. As an additional aid in routine work, it is possible to purchase an automated workbench that will produce the samples dissolved in the appropriate solvent in an NMR tube starting from a solid specimen in a screw-capped bottle and that will also dispose of samples safely and wash the NMR tube. It is possible to foresee the demise of the glass NMR tube in laboratories that require high sample throughput. This can now be achieved using a flow probe type of NMR detector and automatic sample handling robots that take samples from 96-well plates. This is an extension of the technology used for direct coupling of chromatography, such as HPLC, to NMR spectroscopy (see ^1H MAS NMR Spectroscopy of Tissues).

Magnetic Field Optimization

Even though modern high-resolution magnets have very high field stability and homogeneity, this is not sufficient

for chemical analysis, in that it is necessary to resolve lines to about a width of 0.2 Hz, and at 800 MHz, this represents a stability of one part in 4×10^9 . This performance is achieved in three ways: first, by locking the magnetic field to the RF to ensure that successive scans are coregistered; second, by improving the homogeneity of the magnetic field; and finally, by sometimes spinning the sample tube.

Usually deuterated solvents are used for NMR spectroscopy to avoid the appearance of solvent peaks in the ^1H spectrum. Deuterium is an NMR active nucleus, and the spectrometer will contain a ^2H channel for exciting and detecting the solvent resonance. In a separate set of circuits, a ^2H transmitter frequency is generated, fed to the probe, usually to the ^1H coil that is double-tuned to accept the ^2H frequency, and the ^2H NMR signal is detected in the normal fashion and shown on the computer. Internally, it is also phased in such a way to produce a dispersive line shape and the field is adjusted so that this peak is always exactly at resonance (i.e., at a null) by means of a feedback loop. If a field drift occurs, caused by an inherent magnet drift or room-temperature fluctuations, then the signal is detected as either a positive or a negative voltage depending on the direction of the drift, and the field is corrected by special coils to return the voltage to zero. In special cases such as when ^2H spectra are to be measured, a ^{19}F -based lock signal can be used. This is known as a 'field-frequency lock' and it means that successive scans in a signal accumulation run are registered exactly.

To improve the homogeneity of the magnet, an assembly of coils is inserted into the magnet bore (shim coils). These consist of about 20–40 coils specially designed so that adjustable currents can be fed through them to provide corrections to the magnetic field in any combination of axes to remove the effects of field inhomogeneity. The criterion of the best homogeneity is based on the fact that when the ^2H lock signal is the sharpest (i.e., the most homogeneous field) the peak signal will be at its highest. The currents in the shim coils are usually adjusted, therefore, to give the highest lock signal. Alternatively, it is possible, although less common, to 'shim' on the ^1H NMR signal. These coils generate magnetic field gradients in very specific directions to counteract any gradients from the main magnet. Some are optimized with the sample stationary and others with the sample spinning, the latter acting along the field axis (usually denoted as z). Many of the shim gradients interact with each other so that much iterative adjustment is necessary.

If, in addition, the NMR probe contains x , y and z gradient coils for applying pulsed field gradients (*see* Magnetic Field Gradients in High Resolution NMR; MRI Theory), an image of the homogeneity can be obtained by conducting an MRI experiment on a strong

sample such as water. Using this map it is possible to compute in just a few iterations the corrections necessary to optimize the homogeneity. This is known as gradient shimming and is now largely computer-controlled in modern spectrometers.

To further improve the NMR resolution, NMR spectra are sometimes measured with the sample tube spinning at about 20 Hz. This can introduce signal sidebands at the spinning speed and its harmonics, and on modern high-field machines with improved resolution, this is becoming less necessary and is undesirable in some cases.

Excitation, Detection, and Computer Processing of NMR Signals

The NMR detector system or probe is inserted into the magnet. The probe contains tunable RF coils for excitation of the nuclear spins and detection of the resultant signals as the induced magnetization decays away. It is usually capable of measuring NMR spectra over a range of temperatures, typically 125–475 K.

Most modern spectrometers have three frequency channels: one for observation, one for decoupling, and one for providing a field-frequency lock usually based on the ^2H resonance of the solvent. The RF signal generation is derived ultimately from a digital frequency synthesizer that is gated and amplified to provide a short intense pulse. This pulse can be rectangular in shape with respect to time or can be shaped to provide any specific properties required. Pulses have to be of short duration because of the need to tip the macroscopic nuclear magnetization by typically 90° or 180° and at the same time to provide uniform excitation over the whole of the spectral range that is appropriate for the nucleus under study (*see* NMR Principles). Thus, for ^{13}C NMR, for example, where chemical shifts can cover > 200 ppm, this requires a 25 kHz spectral width on a spectrometer operating at 500 MHz for ^1H , which corresponds to 125 MHz for ^{13}C . To cover this range uniformly, a 90° pulse should be $< 10 \mu\text{s}$. If only a small part of the whole spectrum needs to be excited, then 'weak' pulses (i.e., of longer duration) can be used.

The RF pulse is fed to the NMR probe containing one or more coils that can be tuned and matched to the required frequency; this tuning changes from sample to sample because of the different properties, such as the solution dielectric constant. This was originally achieved using a power reflection meter but is now largely done electronically using a so-called wobble frequency generator, allowing the observation of the nature of the frequency dependence of the tuning. NMR probes are now commercially available with an automatic tuning system, avoiding the need for any operator. The receiver is blanked off during the pulse and for a short

period afterwards, which allow the pulse amplifier to recover. The receiver is then turned on to accept the NMR signal, which is induced in the coil as the nuclei precess about the field and decay through their relaxation processes. The detection coil is wound on a former as close as possible to the sample to avoid signal losses and is oriented with its axis perpendicular to the magnetic field. In a superconducting magnet, the sample tube is aligned along the field, and this coil axis is therefore at right angles to the field. A simple solenoid that would provide the best S/N is thus not possible, and consequently most detector coils are of the saddle type.

The weak NMR signal is amplified using a preamplifier situated as close to the probe as possible, and then also in the main receiver unit where it is mixed with a reference frequency and demodulated in several stages, leaving the FID as an oscillating voltage in the kilohertz range. This signal is then fed to an analog-to-digital converter (ADC), and at this point, the analog voltage from the probe is converted into a digital signal for data processing. ADCs are described in terms of their resolution usually based on the number of bits of resolution, that is, a typical high-field NMR FID is digitized to a resolution of 16 bits or one part in 2^{16} or 65 536. This digital signal can then be manipulated to improve the S/N or the resolution by multiplying the FID by an appropriate weighting function before the calculation of the digital FT.

If only one ADC is used to collect the NMR FID, it is not possible to distinguish positive frequencies from negative frequencies with respect to the pulse frequency. For this reason, the carrier frequency used to be set to one edge of the spectral region of interest to make sure that none of the NMR peaks were 'aliased,' that is, folded into the spectral region from outside it. This had the disadvantage of allowing all of the noise on the unwanted side of the carrier to be aliased onto the noise in the desired spectral region, hence reducing the final S/N by $\sqrt{2}$. To overcome this problem, it is now universal to collect two FIDs separated in phase by 90° using either two ADCs or one ADC multiplexed to two channels. This approach allows the distinction of positive and negative frequencies and means that the carrier can be set in the middle of the spectrum, the hardware filters correspondingly reduced in width by a factor of 2, and S/N increased by $\sqrt{2}$. This process is termed quadrature detection.

In modern NMR spectrometers, the electronics are largely digital in nature, thus providing greater opportunities for computer control and manipulation of the signals. This includes the use of oversampling and digital filtering to improve the dynamic range of the signal acquisition. Modern NMR spectrometers usually have two separate computer systems. One is dedicated to the acquisition of the NMR FID and operates in background so that all necessary accurate timing requirements can be met. The FID is transferred, either at the end of the

acquisition or periodically throughout it to enable inspection of the data, to the host computer for manipulation by the operator. These computers are based on modern operating systems such as UNIX, Linux, or Windows. Typical operations include manipulations of the signal-averaged FID by baseline correction to remove DC offset, multiplication by continuous functions to enhance S/N or resolution, linear prediction reconstruction of parts of the FID, FT, phase correction, baseline correction of the frequency spectrum, calculation and output of peak lists, calculation and output of peak areas (integrals), and plotting or printing of spectra (*see* NMR Data Processing). It is common to have a separate computer workstation solely for data inspection and manipulation, networked to the host computer. This may be the same model as the host computer but is often an industry standard model from a third-party supplier. NMR data processing software can also be purchased from a number of companies other than the instrument manufacturers, which often have links to document production software or provide output of NMR parameters for input into other packages such as those for molecular modeling.

Decoupling

In many NMR experiments, secondary RF irradiation is applied to perturb NMR state populations or to remove J-coupling splittings (this is known as decoupling). Early experiments generally used a single frequency for the irradiation, but with the advent of ^{13}C NMR spectroscopy, it was advantageous to decouple all the ^1H - ^{13}C interactions to leave each ^{13}C signal as singlet. The S/N in the spectrum is thus boosted not only by the collapse of a multiplet into a single line but also by a population transfer effect known as the nuclear Overhauser enhancement (NOE) effect. This was known as noise decoupling or more recently as broadband decoupling. Various pulse schemes have been generated to achieve this bandwidth of frequencies required for such decoupling. More recently with the advent of inverse detection where the heteronucleus such as ^{13}C is detected indirectly using ^1H NMR spectroscopy (*see* the following text), the broadband decoupling has to cover both the ^1H chemical shift range and the heteronuclear shift range that is usually much greater in frequency terms. Again special pulse sequences have been developed such as a popular one called GARP. The RF is applied usually through a separate RF channel to the transmitter power but it goes to the same coil in the probe.

Multiple Pulse Experiments and Multidimensional NMR

So far everything described applies to the basic one-dimensional NMR experiment when the nuclear spin system is typically subjected to a 90° pulse and the FID

collected. A wide variety of experiments exist in the literature and are routinely applied to measure NMR properties such as relaxation times T_1 , T_2 , and $T_{1\rho}$, which can be related in some cases to molecular dynamics. These experiments involve the use of several pulses separated by timed variable delays and they are controlled by pulse programs written in a high-level language for ease of understanding and modification. The computer system will have software to interpret the data and calculate the relaxation times using least squares fitting routines (*see* NMR Pulse Sequences; NMR Relaxation Rates).

Such pulse programs are also used to enable other special one-dimensional experiments such as saturation or nonexcitation of a large solvent resonance (these are different in that the former method will also saturate NH or OH protons in the molecules under study through the mechanism of chemical exchange) (*see* Solvent Suppression Methods in NMR Spectroscopy), or the measurement of NOE effects, which are often used to provide distinction between isomeric structures or to provide estimates of internuclear distances (*see* Nuclear Overhauser Effect). Pulse programs are also used for measuring NMR spectra of nuclei other than ^1H and sometimes in order to probe connectivity between protons and the heteronucleus. In this case, pulses or irradiation can be applied on both the heteronucleus and ^1H channels in the same experiment. The most common use is in ^{13}C NMR where all spin-spin couplings between the ^{13}C nuclei and ^1H nuclei are removed by decoupling (*see* the preceding text). This involves broadband irradiation of all of the ^1H frequencies while observing the ^{13}C spectrum. Alternatively, it is possible to obtain the effect of broadband decoupling more efficiently by applying a train of pulses to the ^1H system, which is known as composite pulse decoupling.

More recently, a whole range of experiments have been developed that detect low-sensitivity nuclei such as ^{13}C or ^{15}N indirectly by their spin coupling connectivity to protons in the molecule. This involves a series of pulses on both ^1H and the heteronucleus but allows detection at the much superior sensitivity of ^1H NMR. Special probes have been developed for such 'indirect detection' experiments in which the ^1H coil is placed close to the sample and the heteronucleus coil is placed outside it, the opposite or 'inverse geometry' to a standard heteronuclear detection probe.

Multidimensional NMR

The one-dimensional NMR experiment is derived by measuring the FID as a function of time. If the pulse program also contains a second time period that is incremented, then a second frequency axis can be derived from a second FT. This is the basis for 'two-dimensional'

NMR and its extension to three or even four dimensions. For example, a simple sequence such as

$$90^\circ(^1\text{H}) - t_1 - 90^\circ(^1\text{H}) - \text{collect FID for time } t_2,$$

where t_1 is an incremented delay, results after double FT with respect to t_1 and t_2 in a spectrum with two axes, each corresponding to the ^1H chemical shifts. This is usually viewed as a contour plot with the normal one-dimensional spectrum appearing along the diagonal and any two protons that are spin coupled to each other giving rise to an off-diagonal contour peak at their chemical shift coordinates. This simple experiment is one of a large family of such correlation experiments involving either protons alone or heteronuclei. The extension to higher dimensions has already been exploited to decrease the amount of overlap by allowing spectral editing and the spreading of the peaks into more than one dimension. Hardware and software in modern NMR spectrometers allow this wide variety of experiments (*see* Two-dimensional NMR Methods).

The increasingly complex pulse sequences used today rely on the ability of the equipment to produce exactly 90° or 180° or any other angle pulses. One way to do this is to provide trains of pulses that have the desired net effect of, for example, a 180° tip, but that are compensated for any mis-setting. An example of such a 'composite pulse' is $[90_x^\circ - 180_y^\circ - 90_x^\circ]$ that provides a better inversion pulse than a single 180° pulse. Many complex schemes have been invented for both observation and decoupling (especially for low-power approaches that avoid heating the sample). The use of 'phase cycling' is a universal approach to removing artifacts caused by electronic imperfections, and it is also used to simplify spectra by editing out undesired components of magnetization. This allows the operator to choose the phase of any RF pulse and of the receiver, and cycling these phases in a regular fashion controls the exact appearance of the final spectrum.

So far only pulses that excite the whole spectrum (hard pulses) have been described. For spectral editing purposes or to prove some NMR spin connectivity, it can be very convenient to excite only part of a spectrum, possibly only that corresponding to a given chemical shift or even one transition in a multiplet. This approach termed 'selective excitation' is achieved by using lower power pulses applied for a longer period of time (e.g., a 10 ms 90° pulse will only cover 25 Hz). Such selective pulses are often not rectangular like hard pulses but can be synthesized in a variety of shapes such as sine or Gaussian because of their desirable excitation frequency profiles. Modern research spectrometers can include such selective, shaped pulses in pulse programs.

Pulsed Magnetic Field Gradients

Another development that has also come to high-resolution NMR spectroscopy from MRI is the inclusion of pulsed magnetic field gradients into NMR pulse sequences. These gradients are generated by special amplifiers that send power to gradient coils built into the NMR probe, and these coils can be aligned along the three orthogonal axes x , y , and z , where z is the main magnetic field direction. The gradients are switched on and off for predetermined periods in the pulse sequence and are used for various purposes. The switching can be essentially instantaneous (square gradients) or gradual (shaped gradients, typically sine or Gaussian shapes are used). The simplest use is to destroy coherent magnetization by inducing a large field inhomogeneity across the sample. Second, if trains of gradient pulses are used, then the magnetization can be manipulated to select or remove particular spin coherences as they are called, to give edited NMR spectra. Finally, in special pulse sequences, spin positions can be effectively labeled because of the gradient value, and if equal and opposite gradients are applied later, any loss of signal intensity relates to the diffusion coefficient of the molecule giving rise to the NMR peak.

Instruments for Special Applications

NMR of Solids

Although ^1H high-resolution NMR spectroscopy is possible in the solid, most applications have focused on heteronuclei such as ^{13}C . High-resolution studies rely on very short pulses, so high-power amplifiers are necessary. Similarly, because of the need to decouple ^1H from ^{13}C and thereby to remove dipolar interactions not seen in liquid state, high-power decoupling is required. However, the major difference between solution- and solid-state high-resolution NMR studies lies in the use of 'magic angle spinning' (MAS) in the latter case. This involves spinning the solid sample packed into a special rotor at an angle of $54^\circ 44'$ to the magnetic field. This removes broadening due to any chemical shift anisotropies that are manifested in the solid-state spectrum and any residual ^1H - ^{13}C dipolar coupling not removed by high-power decoupling. Typical spinning speeds are in the low kilohertz range (5 kHz is 300 000 rpm), although higher speeds up to 35 kHz, or as recently demonstrated, 70 kHz, are possible and necessary in some cases (*see* High Resolution Solid State NMR, ^{13}C ; Solid State NMR, Methods). For studies of nuclei that have spin quantum numbers $> 1/2$, so-called quadrupolar nuclei, in order to remove line broadening effects, more complex spinning schemes have been developed, including spinning about two axes simultaneously with one spinner inside the other.

MAS NMR probes that also include a ^2H channel for a field-frequency lock are known as high-resolution MAS probes. These have been used for studies of pharmaceutical compounds bound to synthetic resin beads and for analysis of tissue samples. Because such samples already exhibit considerable molecular motion unlike rigid solids, the anisotropic broadening is much less and simple MAS sample rotation is sufficient to remove the broadening. This means that ^1H as well as heteronuclear NMR spectroscopy is feasible.

NMR Imaging

A whole new specialized subdivision of NMR has developed in the allied disciplines of NMR imaging (magnetic resonance imaging or MRI) and NMR spectroscopy from localized regions of a larger object. MRI applications range from the analysis of water and oil in rocks obtained from oil exploration drilling to medical and clinical studies, and spectroscopic applications include the possibility of measuring the ^1H or ^{31}P NMR spectrum from a particular volume element in the brain of a living human being and relating the levels of metabolites seen to a disease condition. Some experiments on smaller samples can be carried out in the usual vertical-bore superconducting magnets (these experiments are sometimes termed NMR microscopy), but studies are more often performed in specially designed horizontal-bore magnets with a large clear bore capable of taking samples up to the size of adult human beings. Because of the large bore, they operate at lower field strengths compared to analytical chemical applications, and typical configurations would be 2.35 T with a 40 cm bore or 7.0 T with a 21 cm bore. Clinical imagers generally utilize magnetic fields up to 2 T with a 1 m bore. Imaging relies upon the application of magnetic field gradients to extra coils located inside the magnet bore in all three orthogonal axes including that of $\mathbf{B}_0$ and excitation using selective RF pulses. Virtually all clinical applications of MRI use detection of the ^1H NMR signal of water in the subject, with the image contrast coming from variation of the amount of water or its NMR relaxation or diffusion properties in the different organs or compartments being imaged. Very fast imaging techniques have been developed that allow movies to be constructed of the beating heart or studies of changes in brain activity as a result of light or aural stimulation to be conducted.

In addition, the same technology can be used for *in vivo* NMR spectroscopy where ^1H or ^{31}P are the main nuclides observed, although ^{13}C has also been studied. Localization of the spectra to specific regions of a subject (e.g., a volume element in a human brain region) is achieved by taking advantage of magnetic field gradients in the presence of selective pulses; many pulse sequences have been designed for this purpose. Crude localization

has also been achieved using a simple surface coil over the region of interest (*see In Vivo NMR Methods; MRI Applications, Clinical; MRI Instrumentation; MRI of Oil/Water in Rocks*).

Benchtop Analysis

Specialist tabletop machines are available that can be used for routine analysis in the food and chemical industries. They operate automatically at typically 20 MHz for ^1H NMR using internally programmed pulse sequences and are designed to give automatic printouts of analytical results such as the proportion of fat to water in margarine or the oil content of seeds.

Remote Sensing

Another application has been the development of specialist NMR instruments with single-sided magnets. These are portable and can thus be used for remote sensing. They are used for plant studies in the field or in industrial settings such as measuring flow in pipes, or indeed testing the pipes themselves. One of the most unusual developments has been that of instruments for insertion into oil well holes in order to prospect for oil.

Future Trends

Higher Sensitivity

The most straightforward way to increase NMR sensitivity and hence to improve detection limits is to increase the magnetic field strength. This can be an expensive option. At present 950 MHz detection for ^1H NMR is the current commercial limit and the first machines at this field have now been delivered. Higher fields must be on the way, and clearly an break-through figure would be the 1 GHz ^1H NMR spectrometer. In fact, Bruker have just announced the manufacture of a 1000 MHz spectrometer with a persistent superconducting magnet, and the first one should be delivered to Lyon, France in July 2009. Although the higher field strengths provide greater spectral dispersion and yield better sensitivity, it may be that some applications involving heavier nuclei are less suited to such high fields because of the field dependence of certain mechanisms of nuclear spin relaxation that could cause an increased line broadening and hence lower peak heights and detectability. A second way to improve sensitivity without increasing the spectral dispersion is to employ NMR probe detectors cooled to cryogenic temperatures, so-called cryo-probes or cold probes. These are now commercially available for many observation frequencies and are becoming widely used. Another important approach is the use of nuclear polarization methods whereby the NMR signal strength is boosted by increasing the population difference between

the excited and ground spin states. This can be achieved in a number of ways, including the use of free radicals with unpaired electron spins or by polarizing certain gases (notably xenon) and transferring the polarization to the nucleus of interest. Using such approaches, gains in sensitivity of orders of magnitude have been achieved.

New NMR Pulse Experiments

Many complex multidimensional experiments exist in the literature, and developments, through such approaches as selective excitation, allow the reduction of the enormous data matrices that result. This also means that new methods of detecting only the desired information in complex spectra are becoming possible through such approaches as the detection of ^1H NMR resonances only from molecules containing certain isotopes of other nuclei. The use of pulsed magnetic field gradients in the high-resolution NMR area provides new ways of editing complex spectra with improved data quality and acquisition speed. This technology has already found widespread application, and will continue to expand, for example, in the measurement of diffusion coefficients and other forms of molecular mobility (*see Diffusion Studied Using NMR Spectroscopy; Magnetic Field Gradients in High Resolution NMR*). Many complex multipulse experiments are used for probing the three-dimensional structure of macromolecules such as proteins and nucleic acids with a precision similar to that of X-ray diffraction, but in solution. Another application is to study macromolecule–small-molecule ligand interactions as these can lead to insights into drug effects and have implications for drug design. These experiments are usually multidimensional in nature and can take several days of data collection time to complete. A number of ways of speeding up these time-consuming experiments have been published.

Coupled Techniques

The coupling of HPLC to NMR has been shown to be of great use in separating and structuring components of complex mixtures such as drug metabolites in body fluids. This technique has been extended to other chromatographic techniques such as SFC and to the use of nuclei other than ^1H or ^{19}F that have been the basis of most studies so far because of their high NMR sensitivity. The direct coupling of capillary electrophoresis (CE) and capillary electrochromatography (CEC) to NMR has also been developed. The hyphenation of HPLC with both NMR spectroscopy and mass spectrometry has been achieved and commercial systems are now available. It is expected that a wealth of applications based on these technologies, such as the identification of drug metabolites, will be forthcoming (*see Drug Metabolism*

Studied Using NMR Spectroscopy; Hyphenated NMR, Methods and Applications).

Symbols

eq	electric field gradient strength
e^2qQ/h	quadrupolar coupling
eQ	quadrupole moment strength
I	spin quantum number
T_1	longitudinal relaxation time
T_2	transverse relaxation time
τ	correlation time for molecular motion (s)
ω	Larmor frequency (rad s^{-1})

The alkali metals, lithium, sodium, potassium, rubidium and caesium all possess NMR active nuclei, all of which are quadrupolar.

- Lithium has two NMR active isotopes, ^6Li (7.4%) and ^7Li (92.6%), of which ^7Li is the isotope of choice due to its higher magnetogyric ratio and natural abundance. Both isotopes are available in isotopically enriched form making NMR tracer studies relatively easy.
- Sodium has only one NMR active nucleus, ^{23}Na (100%).
- Potassium has two NMR active isotopes, ^{39}K (93.1%) and ^{41}K (6.9%), of which ^{39}K is the isotope of choice due to its much greater natural abundance and ^{41}K is observable only with the greatest difficulty.
- Rubidium has two NMR active isotopes, ^{85}Rb (72.15%) and ^{87}Rb (27.85%), of which ^{87}Rb is the isotope of choice due to its much higher magnetogyric ratio despite its lower natural abundance.
- Caesium has only one NMR active nucleus, ^{133}Cs (100%).

Lithium is important as the treatment of choice for manic-depressive psychosis and this has provoked a wide variety of NMR studies in an endeavour to probe its mode of action. Organolithium compounds are used extensively in synthetic organic chemistry and as industrial catalysts, especially in polymerization reactions.

Both sodium and potassium are essential for life. Potassium is the major intracellular cation in most living cells, with sodium having the second highest concentration. These concentrations are generally reversed in extracellular fluids. The concentration differences across the cellular membrane are maintained by ion pumps, the

most important of which is Na/K/ATPase. This enzyme pumps three sodium ions out of the cell and two potassium ions in for the consumption of one molecule of ATP. This enzyme consumes about one-third of the ATP produced in the human body, emphasizing the importance of maintaining the concentration gradients of these ions for life. In addition, large numbers of enzymes require the presence of sodium or potassium for them to function by mechanisms such as symport or antiport. The human need for sodium chloride as a part of the diet is recognized in many proverbs and sayings in common use and its usage for the word 'salary' is a reminder that salt has been used in the past as a form of payment.

Although the chemistry of rubidium is close to that of potassium it cannot be used as a substitute for potassium in biological systems *in vivo*; however, it has been used in studies of perfused organs and cellular systems. The same applies to caesium for similar reasons. These metals can be taken into biological systems where they generally replace potassium, but the ingestion of large amounts of the salts of either metal has severe physiological consequences leading in extreme cases to death.

Many reasons exist, therefore, for the development and implementation of NMR methods for the study of the alkali metals.

Nuclear Properties

The nuclear properties of the NMR active isotopes of the alkali metals are presented in Table 1.

Quadrupolar Relaxation and Visibility

The NMR spectra of the alkali metals are dominated by the fact that all the isotopes are quadrupolar. Effective use of alkali metal NMR requires an understanding of the resulting quadrupolar interactions and of the best ways to make use of them and to avoid their pitfalls. Many of the problems that arise and solutions adopted are similar to those involved with the halogens. Quadrupolar nuclei have an asymmetric distribution of charge which gives rise to an electric quadrupole moment. Apart from when the nucleus is in an environment with cubic or higher symmetry, the quadrupole moment interacts with the electric field gradient (EFG) experienced by the

Table 1 Nuclear properties of the alkali metals

Isotope	Spin, <i>I</i>	Natural abundance (%)	Magnetogyric ratio, $\gamma/10^7$ (rad T ⁻¹ s ⁻¹)	Quadrupole moment $Q/10^{-28}$ (m ²)	NMR frequency, Ξ (MHz)	Relative receptivity, D^c
⁶ Li	1	7.42	3.937	-8×10^{-4}	14.716	3.58
⁷ Li	3/2	92.58	10.396	-4.5×10^{-2}	38.864	1.54×10^3
²³ Na	3/2	100	7.076	0.12	26.451	5.25×10^2

nucleus, giving rise, among other things, to quadrupolar relaxation. The strength of the quadrupolar interaction between the quadrupole moment (eQ) and the electric field gradient (eq) is given by the quadrupolar coupling e^2qQ/b . This can take values from very small to hundreds of MHz, depending on the magnitudes of Q and q .

In solution, modulation of the EFG at the quadrupolar nucleus by isotropic and sufficiently rapid molecular motions (where $\omega\tau \ll 1$) leads to relaxation according to the expression:

$$\frac{1}{T_1} = \left(\frac{3}{40}\right) \left[\frac{(2I+3)}{I^2(2I-1)}\right] \times \left(\frac{1+\eta^2}{3}\right) \left(\frac{e^2qQ}{h}\right)^2 \tau_c$$

where η is the asymmetry parameter associated with the EFG.

The alkali metal ions in solution are subject to relatively low quadrupolar interactions. This is particularly true for ⁶Li and ⁷Li and for ¹³³Cs, which have inherently low quadrupole moments. Indeed ⁶Li and ¹³³Cs have the two lowest known quadrupole moments and ⁶Li is often referred to as an 'honorary' spin $\frac{1}{2}$ nucleus. In aqueous solution the ions are solvated by charge-dipole interactions with the water molecules. At any one instant the pattern of water molecules around the cation does not have spherical symmetry but is always close to it. Thus the quadrupolar couplings are low but are never zero. Typically, in aqueous solution and in the absence of extraneous influences, both isotopes of lithium show Li⁺ line widths of <1 Hz, Na⁺ and K⁺ show a line width of ca. 12 Hz, both rubidium isotopes show line widths of ca. 140–150 Hz and ¹³³Cs shows a line width of ca. 1 Hz.

Because of the low values of the quadrupole moments for both isotopes of lithium, dipolar relaxation becomes important. In aqueous solution at ambient temperature, dipolar relaxation accounts for over 75% of the relaxation of ⁷Li ($T_1 \sim 20$ s) and almost 100% of ⁶Li ($T_1 \sim 170$ s).

In D₂O solution with no ¹H available for dipolar relaxation and virtually no quadrupolar mechanism available, the relaxation time of ⁶Li becomes very long ($T_1 \sim 830$ s). In contrast, it appears that despite the low quadrupole moment of ¹³³Cs, dipolar relaxation does not contribute significantly.

In cases where molecular motion is restricted ($\omega\tau$ is not $\ll 1$) the situation is more complex. Such cases arise when the alkali metal is bound to the surface of a large molecule such as a protein or membrane surface and thereby has its motion restricted. The quadrupolar interaction with the nucleus shifts the energies of the Zeeman levels according to the square of the quantum number to a first approximation. Thus, the energy level splittings for a nucleus with $I = \frac{3}{2}$ (e.g. ⁷Li, ²³Na, ³⁹K and ⁸⁷Rb) become as illustrated in **Figure 1**. With rapid isotropic motion, as described in the preceding paragraphs, the multiple line pattern will collapse into a single line. In the absence of rapid isotropic motion the relaxation rate of the outer transitions, which combine to have 60% of the total intensity, is different from that of the inner transitions, which has 40% of the total intensity. The frequencies of the outer transitions also shift from the inner transitions (dynamic frequency shift). There are three principal consequences of these changes for cases where the motion of the cation is restricted. First, line shapes become a double and not a single Lorentzian; secondly, two relaxation times are apparent; and finally, where the more rapid relaxation time becomes very short, partial or total invisibility of the signal from the outer transitions may occur. An excellent review of quadrupolar relaxation effects is given in the review by Springer given in the Further reading section.

Biological Applications

Contrast Reagents

One of the main problems in using NMR to study the alkali metals in biological systems is that the chemical

Figure 1 Changes in the energy levels for a spin $\frac{3}{2}$ nucleus subject to a quadrupolar interaction. *Note:* The shifts in energy levels shown are exaggerated for clarity.

shifts of the aqueous ions are essentially independent of the ion's surroundings in all cases except for $^{133}\text{Cs}^+$, making differentiation of intra- and extracellular cations difficult. This problem can be met by using a contrast reagent (either a shift or a relaxation agent) in one of the compartments, normally extracellular. A large number of aqueous shift reagents have been employed. They all work on the same principle, that a paramagnetic lanthanide, typically dysprosium, is enclosed in a complex by a ligand or ligands, and the resulting complex has several negative charges. With the overall charge on the complex being negative, the alkali metal cations are attracted to the negatively charged species and thereby brought into a region where the paramagnetic interaction induces a chemical shift change. Typical shift reagents for the alkali metals are given in **Table 2**. The resonances of the cations are also broadened by the process, but this broadening has been shown to be largely due the quadrupolar interaction of the cation with the reagent and not due to paramagnetic relaxation. For rubidium, which has a substantial line width that is comparable to the shifts capable of being induced by the best shift reagents, it is preferable to employ a relaxation agent to relax the signal from the extracellular Rb^+ into the baseline noise.

The first important application of alkali metal shift reagents was the use of dysprosium bistrisphosphosphate ($\text{DyP}_3\text{O}_{10})_2^{7-}$ (DyPPP_2) to differentiate between intra- and extracellular ^{23}Na in human erythrocytes. This was

Table 2 Shift reagents for alkali metal cations

Shift reagent	Acid anion
$[\text{Dy}(\text{PPP})_2]^{7-}$	Tripolyphosphate $(\text{P}_3\text{O}_{10})^{5-}$
TmDOTP^{6-}	Thulium 1,4,7,10-tetraazacyclodecane-1,4,7,10-tetrakis(methylenephosphonate)
	
$[\text{Dy}(\text{NTA})_3]^{3-}$	Nitriiotriacetate $[\text{N}(\text{CH}_2\text{COO})_3]^{3-}$
$[\text{Dy}(\text{CA})_3]^{6-}$	Chelidamate
	
$[\text{Dy}(\text{THHA})]^{3-}$	Triethylenetetraminehexaacetate
	
$[\text{Dy}(\text{DPA})_2]^{3-}$	Dipicolinate
	

soon followed by a similar experiment revealing the intracellular signal from ^{39}K . In both cases it seems as if the intracellular metal ions in human erythrocytes are essentially 100% visible. The spectra obtained for the ^{39}K experiment are shown in **Figure 2**.

The maximum shift generated by the shift reagents varies with the alkali metal according to the number of shells of electrons shielding the nucleus from the paramagnetic centre. For example the maximum shifts available from DyPPP_2 are approximately $^7\text{Li}^+$, 40 ppm; $^{23}\text{Na}^+$, 20 ppm; $^{39}\text{K}^+$, 10 ppm; $^{87}\text{Rb}^+$, 4 ppm; $^{133}\text{Cs}^+$, 2 ppm.

The shift reagent DyPPP_2 is commonly used for *in vitro* systems such as vesicles or with isolated erythrocytes. However, it displays considerable toxicity for *in vivo* systems, in which cases the shift reagent TmDOTP^{5-} (see **Table 2**) is preferred. For example during *in vivo* studies of rat kidneys using TmDOTP^{5-} , three $^{23}\text{Na}^+$ signals were resolved, corresponding to intracellular Na^+ , vascular Na^+ and intraluminal Na^+ .

Multiple Quantum Filtration

It has been shown that ^{23}Na double-quantum-filtered NMR spectroscopy can be used to detect anisotropic motion of bound sodium ions in biological systems. The technique is based on the formation of the second-rank tensor when the quadrupolar interaction is not averaged to zero. Isotropically tumbling ^{23}Na , free in aqueous solution, is not seen by these methods. Such techniques allow, for example, the detection of $^{23}\text{Na}^+$ bound to macromolecules such as proteins or membranes or the detection of intracellular $^{23}\text{Na}^+$ if its motion is partially restricted. Triple-quantum-filtered spectra can also be used for similar purposes.

Multiple-quantum-filtered NMR offers the possibility of monitoring the intracellular Na^+ content in the absence of shift reagents provided that three criteria are met: (1) the contribution from intracellular $^{23}\text{Na}^+$ to the multiple-quantum-filtered spectrum is substantial, (2) it responds to a change in intracellular $^{23}\text{Na}^+$ content and (3) the amplitude of the extracellular multiple-quantum-filtered component remains constant during a change in intracellular $^{23}\text{Na}^+$ content.

Lithium NMR

The use of Li^+ salts as the preferred treatment for manic-depressive psychosis has spurred on the use of ^7Li NMR in biological systems, particularly work on cellular systems. The use of the shift reagent DyPPP_2 for ^{23}Na and ^{39}K to separate intra- and extracellular signals in human erythrocytes was rapidly followed by similar experiments with $^7\text{Li}^+$. The object of these experiments was to determine lithium transport rates across the erythrocyte membrane as a model for the blood-brain

Figure 2 ^{39}K NMR spectra recorded at 16.8 MHz of (a) resuspension medium containing 60 mM K^+ , 6 mM Dy^{3+} , and 15 mM tripolyphosphate; (b) human erythrocytes in the same medium; and (c) difference spectrum after the subtraction of 0.3 of the intensity of spectrum (a) from spectrum (b). For each spectrum 20 000 free induction decays were collected in approximately 20 min. Reproduced from Brophy PJ, Hayer MK, and Riddell FG (1983) Measurement of intracellular potassium ion concentration by NMR. *Biochemical Journal* 210: 961 with permission from the Biochemical Society.

barrier. Comparisons were made of the transport rates of $^7\text{Li}^+$ into and out of the erythrocytes of manic-depressive patients being treated with Li^+ , with those of normal controls. These experiments have demonstrated that at extracellular concentrations ranging from 2 to 50 mM, the efflux rate from the erythrocytes of the patients was significantly slower than for those of the controls. Moreover, the experiments have shown that the abnormal transport rate is a consequence of Li^+ treatment and is not a marker for the illness. Similar experiments have been carried out with other cellular systems including astrocytomas, neuroblastomas, rat hepatocytes and cultured Swiss Mouse 3T3 fibroblasts. The work on astrocytomas, an immortalized cell line from a human brain cancer, allowed visualization of Li^+ inside the cells which were supported on microcarrier beads (Figure 3) and showed that there is an active Li^+ extrusion pump present in these cells and, therefore, that there must also be a Li^+ pump present in astrocytomas in the brain.

It is widely believed that the enzyme interacting with Li^+ when it acts to control manic-depressive psychosis is inositol monophosphatase. $^7\text{Li}^+$ NMR signals from Li^+ bound to the inositol monophosphatase enzyme have been observed. This suggests that $^7\text{Li}^+$ NMR could make an important contribution to the study of this and other lithium-sensitive enzymes.

NMR imaging techniques have been applied to study the concentrations and the pharmacokinetics of Li^+ in various parts of the human body. Such experiments have shown that the concentration of Li^+ in the brain and muscle is lower than that in the blood serum. Interestingly, they have also shown that after ingestion of Li^+ there is lag in the uptake of Li^+ into the brain. Maximum concentrations of Li^+ in the brain occur several hours after the maximum concentration in the serum has been reached. Such experiments point towards better treatment regimes for patients.

Sodium, Potassium, Rubidium and Caesium NMR

A very substantial body of literature exists on the use of ^{23}Na and ^{39}K NMR to study cardiac function. Such experiments are typically performed on isolated perfused rat hearts, although hearts from other species including guinea pigs and dogs have also been used. Often the experiments involve shift reagents, although more recently multiple quantum filtration has been extensively used to differentiate between pools of ions. During ischaemia (low or zero blood flow which mimics a heart attack) there is an accumulation of intracellular sodium, cellular swelling and energy deficiency that participate in the transition to irreversible ischaemic injury. Such changes can be followed readily by a combination of ^{23}Na and ^{31}P NMR techniques. These experiments have

Figure 3 ^7Li NMR spectra of astrocytomas on microcarrier beads in a buffer containing dysprosium tripolyphosphate shift reagent. Each spectrum is the sum of 48 acquisitions recorded at 194 MHz, $[\text{Li}^+]_{\text{out}} = 10$ mM. Reprinted from Bramham J, Carter AN, and Riddell FG (1996) The uptake of Li into human 1321 NI astrocytomas using ^7Li NMR spectroscopy. *Journal of Inorganic Biochemistry* 61: 273–284, with permission from Elsevier Science.

provided valuable information on the behaviour of hearts under conditions of ischaemia and their recovery afterwards during reperfusion. They provide valuable information on methods for the resuscitation of ischaemic hearts and their protection against hypoxic injury. Although not present in normal biological systems in other than trace amounts, Rb^+ and Cs^+ have been used on several occasions as K^+ analogues in the experiments mentioned in the preceding text, thus extending the range of nuclei available for study. Other similar experiments have been performed on hearts from

genetically hypertensive rats. Similar experiments have been performed on other organs such as kidney and liver from small animals.

Studies of $^{23}\text{Na}^+$ in cellular systems have been performed on cells such as superfused isolated rat cardiomyocytes, *Methanobacterium thermoautotrophicum*, porcine vascular endothelial cells, the halotolerant bacterium *Brevibacterium* sp., *Escherichia coli*, murine TM3 Leydig and TM4 Sertoli cell lines, and mouse 3T3 fibroblasts. These experiments have been employed to determine the NMR visibility of $^{23}\text{Na}^+$, its intracellular concentration, membrane transport properties and dynamics and its ionic mobility inside the cells. ^{23}Na NMR studies have contributed to the study of Na/K/ATPase.

Since the principal cytoplasmic cation is K^+ , NMR experiments on $^{39}\text{K}^+$ in cellular systems should give valuable information on the intracellular environment. That they have been used much less frequently than experiments on $^{23}\text{Na}^+$ is because of the lower receptivity of ^{39}K . The utility of $^{39}\text{K}^+$ studies is shown by work on $^{39}\text{K}^+$ from *E. coli* after plasmolysis. The $^{39}\text{K}^+$ signals are 100% visible and show biexponential relaxation, with both components relaxing very rapidly. The result was attributed to a substantial interaction between the $^{39}\text{K}^+$ and the polynegatively charged surface of the ribosomes.

The uptake of Rb^+ into human erythrocytes has been studied by ^{87}Rb NMR using the relaxation agent LaPPP₂ to contrast the two pools of Rb^+ . Uptake was linear over a 24-h period.

With $^{133}\text{Cs}^+$ NMR there is no need for a contrast reagent to separate the intra- and extracellular signals, since the chemical shifts of the intra- and extracellular signals are well separated. Variations of the phosphate concentration in the suspension buffer are sufficient for this purpose. Uptake of $^{133}\text{Cs}^+$ into human erythrocytes was observed to be linear with a rate of 0.33 mM h^{-1} at an extracellular Cs^+ concentration of 10 mM. When the cells were removed to a Cs^+ -free buffer they retained the Cs^+ , indicating that there is no transport mechanism available for the removal of Cs^+ from the cells. Cs^+ was shown to replace K^+ inside the cell. The favourable properties of $^{133}\text{Cs}^+$ as indicated in the preceding text, primarily its chemical shift range without the use of shift reagents and its low quadrupolar interactions, have led to its use as an analogue of K^+ in several studies of its tissue compartmentation.

Mediated Membrane Transport

A variety of NMR methods exists for the study of the mediated transport of alkali metal ions through model biological membranes. Substrates that mediate the transport include the ionophoric antibiotics such as monensin [1], channel forming peptides such as gramicidin and the

peptaibols, other channel forming substrates such as amphotericin and the brevetoxins, or synthetic carriers, for example, those based around crown ether-like skeletons such as [2]. For such experiments large unilamellar vesicles (LUV) formed from phospholipid are prepared and a chemical shift difference between the intra- and extravesicular compartments is established by means of a shift reagent. For rapid exchange of ions across the membrane ($k > 10 \text{ s}^{-1}$) dynamic line broadening provides information on the transport kinetics (Figure 4). For cases where the transport rate is comparable to the relaxation rate a magnetization transfer technique can be employed. In this experiment one of the two signals, normally the extracellular signal, is inverted by a simple pulse sequence. Chemical exchange then causes a time-dependent reduction in the signal of the other resonance. Analysis of signal intensities against time gives the transport kinetics. For relatively slow exchange ($k < 10^{-3} \text{ s}^{-1}$) isotope exchange is used, for $^6\text{Li}/^7\text{Li}$ or $^7\text{Li}/^{23}\text{Na}$. In such experiments the concentration gradients of the cations form the driving force for the transport. Such experiments have provided extremely valuable insights into the kinetics and mechanism of mediated transport. For the ionophoric antibiotics such as monensin they have shown that one ionophore transports one alkali metal and that the rate-limiting step is almost invariably release of the alkali metal ion at the membrane surface. However, several synthetic ionophores, for example ([2], $n=3$, $\text{R}_1=\text{R}_2=\text{C}_{10}\text{H}_{21}$), which transports Na^+ at a rate comparable to that of monensin, exhibit diffusion as the rate-limiting step. For gramicidin, for example, these experiments have confirmed that two molecules are required to come together to form a pore. For the peptaibols the transport has been shown to occur by 'barrel stave' assembly of peptide molecules across the membrane forming a pore inside the 'barrel' that is of sufficiently long duration to allow complete exchange of the intra- and extravesicular media. For the brevetoxins, selectivity for various ions was probed by changing the ions involved in the concentrations gradients. The dependence on cholesterol incorporation in the membrane was studied.

So-called 'bouquet molecules', based on a central crown ether or cyclodextrin unit equipped with pendant arms that are also capable of complexing cations and are long enough to traverse a lipid bilayer, have been studied in vesicles with a Na^+/Li^+ gradient across the membrane using both ^7Li and ^{23}Na NMR. Such systems show a one-for-one exchange of Na^+ for Li^+ (antiport). These molecules were found to transport Na^+ at similar rates in fluid- and gel-state membranes; this suggests that ion passage occurs preferentially by a channel mechanism and not by the carrier mechanism. Monensin, known to operate as a carrier, was shown to transport at a slower rate in a gel-state membrane.

Figure 4 Changes in the ^{23}Na NMR spectra recorded at 21.16 MHz of LUV containing 120 mM NaCl on addition of increasing microlitre amounts of a dilute solution of monensin in methanol at 303 K. The surrounding solution contains 10 mM $\text{Na}_5\text{P}_3\text{O}_{10}$, 70 mM NaCl, and 4.0 mM DyCl_3 . Reprinted from Riddell FG and Hayer MK (1985) The monensin-mediated transport of sodium ions through phospholipid bilayers studied by ^{23}Na -NMR spectroscopy. *Biochimica Biophysica Acta* 817: 313–317, with permission of Elsevier Science-NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

Another interesting aspect of these experiments is their ability to probe the effect of changes in the membrane composition on the transport kinetics. Thus, placing positive and negative charges on the membrane surface causes changes in ionophore-mediated transport rates, and the introduction of pharmaceuticals such as chlorpromazine and imipramine cause changes in the nigericin-mediated Na^+ transport rates.

Chemical Applications

Covalently Bound Lithium

Lithium covalently bound to carbon may be observed by ^7Li NMR in lithium alkyls. In such molecules ^7Li has a small chemical shift range (~ 12 ppm). Tables of chemical shifts and coupling constants are to be found in the review by Günther.

Metal Ion Complexation Studies

Although biological applications have been the major use of alkali metal ion NMR, it has also proved to be valuable for the study of complexation of the alkali metals in host-guest systems by suitably designed ligands, for example the crown ethers and cryptands. Two parameters are important in detecting complexation: chemical shift changes and decreases

[4]

in relaxation times as a result of enhanced quadrupolar interactions.

Often dynamically broadened alkali metal NMR spectra can be seen as a result of exchange between the free and complexed cation. A good example is provided by the dynamic ^7Li and ^{23}Na spectra for the interaction of Li^+ and Na^+ with the pendant arm macrocycle 1,4,7,10-tetrakis(2-methoxyethyl)-1,4,7,10-tetraazacyclododecane [3]. The dynamic ^7Li spectra are shown in **Figure 5**. Evidence of a slowly exchanging 1:1 complex and of a 2:1 complex in rapid equilibrium with the 1:1 complex between calixarene [4] and Na^+ is provided by studies of this system by ^{23}Na and ^1H NMR.

Frequently, when the alkali metal ion is exchanging between the complex and the solution, the temperature variation of T_1 and T_2 for the metal can give information about the exchange kinetics. The complexed ion has a much shorter T_1 (and T_2) value due to strong quadrupolar interactions with the ligand. In the slow exchange limit the observed T_1 value approaches that of the ion free in solution, whilst in the rapid exchange limit the T_1 value is an average of the values for the complexed and free ions. In between these extremes, T_1 follows a sigmoid curve when plotted against $1/T$.

Alkali Metal Anions in Solution: Alkalide Ions

Under conditions of the most rigorous purity and using high-vacuum techniques in dipolar aprotic and similar solvents, the alkali metals yield metal anions (M^-) known as the alkalides. Thus sodium in hexamethylphosphoric

Figure 5 Typical exchange-modified ^7Li NMR spectra recorded at 116.59 MHz of a dimethylsulfoxide solution of solvated Li^+ and [3]. Experimental temperatures and spectra appear on the left of the figure and the best fit calculated line shape and lifetime values on the right. Complexed $^7\text{Li}^+$ appears as the left-hand side, high-frequency peak. Reprinted from Stephens AKW, Dhillon RS, Madbak SE, Whitbread SL, and Lincoln SF (1996) Alkali metal complexes of the pendant arm macrocyclic ligand 1,4,7, 10-tetrakis (2-methoxyethyl)-1, 4, 7, 10-tetraazacyclododecane. An equilibrium and inter- and intramolecular exchange study. *Inorganic Chemistry* 35: 2019–2024, with permission from American Chemical Society.

triamide solutions gives rise to sodide (Na^-) ions. Sodium and rubidium in 1,4,7,10-tetraoxacyclododecane (12-crown-4) give sodide and rubidide ions (**Figure 6**). These anions are most readily identified by their NMR spectra which occur substantially to low frequency of the chemical shift standards of the alkali metal salts in D_2O solution. The alkalide ions are formed by the addition of one electron to the partially filled outermost s orbital. This is expected to lead to a substantial shielding increase, the observation of which is a good indication of the ion formation. Chemical shifts of the alkalide anions vary slightly with solvent and temperature but are near the following values: Na^- , -62 ppm; K^- , -103 ppm; Rb^- , -191 ppm; Cs^- , -280 to -300 ppm.

On the one hand, the spectra of the sodide ion and the potasside ion at low temperatures show relatively sharp line widths, indicative of low ion–solvent interactions suggesting that these ions in solution resemble those in the gas state. On the other hand, at room temperature, the line width of the rubidide ion (~ 1000 Hz vs 140 Hz for Rb^+ in H_2O) indicates that there is quadrupolar broadening and the observed shift falls short of that calculated for a gaseous-like ion, unlike the shifts of the sodide and potasside ions. This strongly suggests that there are interactions between the solvent and the rubidide ion. In the case of caesium dissolved in crown ethers the species Cs^+e^- has also been observed.

Figure 6 ^{23}Na and ^{87}Rb NMR spectra of solutions of sodium and rubidium in 1,4,7,10-tetraoxacyclododecane (12-crown-4). Negative chemical shift values correspond to a decrease in resonance frequency and an increase in nuclear shielding. Reproduced from Holton DM, Edwards PP, Johnson DC, Page CJ, McFarlane W, and Wood B (1984) NMR spectra of Na^+ and Rb^+ in sodium and rubidium in 1,4,7,10-tetraoxacyclododecane (12-crown-4). *Journal of the Chemical Society, Chemical Communications*, 740–741 with permission of The Royal Society of Chemistry.

NMR Spectroscopy of Nucleic Acids, Historical Overview

John C Lindon, Imperial College of Science, Technology and Medicine, London, UK

This article is reproduced from the previous edition, volume 1, pp 1688–1689, © 1999, Elsevier Ltd.

Introduction

The methods used to analyse and assign the NMR spectra of nucleotides and nucleic acids (DNA and RNA) are very similar to those for peptides and proteins. These are the subject of other articles in this Encyclopedia. Individual residues in DNA comprise deoxyribose sugar units connected at C-1' to either cytosine (C) or thymine (T) pyrimidine bases, or to adenine (A) or guanine (G) purine bases. For RNA, the corresponding sugar is ribose and uracil (U) is found instead of thymine. The residues are connected *via* phosphate linkages between the 3'- and 5'-positions of the sugar rings.

Unlike proteins where use is generally made of ^1H , ^{13}C and ^{15}N NMR data, the NMR spectroscopy of nucleotides and nucleic acids uses ^1H , ^{13}C and ^{31}P NMR spectra. In protein NMR studies, it is usual nowadays to prepare the protein extensively labelled with both ^{13}C and ^{15}N and also sometimes with ^2H . These techniques have not been applied so extensively in nucleic acid NMR spectroscopy.

Similar sample preparation methods are used for nucleic acids as for proteins. Nucleic acids are typically dissolved in 90% H_2O –10% D_2O with the corresponding use of appropriate solvent resonance suppression methods for the measurement of ^1H NMR spectra.

An excellent review by James (see 'Further Reading' section) provides an overview of the use of NMR to determine oligonucleotide structure. It covers basic NMR spectral properties, acquisition of inter-proton distance restraints and torsion angle restraints, structure refinement, and assessment of the quality of the structure obtained. Software programs used in the process are also described.

Assignment of NMR Spectra

The usual approach used for proteins is also applied to NMR spectra of nucleic acids. 1D ^1H NMR spectra can be supplemented with COSY or TOCSY spectra to aid spin system connectivities. Separate signals for the exchangeable amino and imino protons can often be observed and the properties of these signals can be very indicative of nucleotide structure. For example, imino protons involved in Watson–Crick base pairing such as

A with T generally resonate in a distinctive window between $\delta 13.0$ and $\delta 14.5$. The ^1H chemical shifts in duplex structures can be different to those for bases in single strands and thus the unwinding of a duplex can be monitored using these shift changes.

Because base protons and sugar protons are separated by a minimum of four bonds, spin couplings are not usually observed between these units and recourse is made to the use of NOE measurements often as 2D NOESY studies. Thus, for example, NOEs observed between the sugar anomeric proton and H-6 and H-8 of a base serve to identify the base and sugar units of a single residue. NOE measurement can also be used to gain information on the sequence of residues in a nucleic acid.

In addition, heteronuclear coupling between ^1H and ^{31}P can be used to make sequential connectivities between residues. This is possible because there is a continuous relay of a series of homonuclear and heteronuclear couplings along the nucleotide backbone.

Variable-temperature studies can be very informative as they give information on the melting and denaturation of duplex structures.

Structural Aspects of Nucleic Acids from NMR Spectroscopy

It is possible to extract information on a wide variety of structural features using NMR spectroscopy of nucleic acids. These include characterization of base pairing, the conformation of the ribose and deoxyribose sugar rings, the torsion angles between sugar rings and the phosphate groups, the orientation of the sugar rings relative to the nucleotide bases, discrimination of right- and left-handed helices and the overall helix structure. In addition, information can be obtained on the location, dynamics and stoichiometry of binding of drugs to nucleic acids. Also, for duplex structures, it is possible to investigate mismatched pairings.

The overall aim is usually to determine the complete 3D structure of a nucleic acid and this is achieved in the same fashion as for protein structures. Thus, the NMR spectra are interpreted in terms of qualitative or semi-quantitative distance information which is then used as a set of constraints for a theoretical calculation of the structure generally based on distance geometry or

restrained molecular dynamics calculations. One of the main problems with this approach, unlike for proteins, is the lack of long-range distance constraints for double-helix structures.

Despite these limitations, a combination of NMR spectroscopy and modelling has been used to derive structures for oligonucleotides, both DNA and RNA fragments, RNA–DNA hybrids and drug–DNA complexes. The review by Rizo and Bruch in the Further Reading section provides references to a wide range of structural and dynamic studies of nucleotides and nucleic acids using NMR spectroscopy.

Ligand binding

Many studies have been undertaken of ligands binding to DNA, and for illustrative purposes a study of the platinum anticancer drugs is highlighted in a review of papers published between 2000 and 2005 where NMR spectroscopy has been applied as the principal method. The paper by Vinje and Sletten (see 'Further Reading' section) gives an overview of the basic NMR techniques particularly relevant for studying interaction between platinum compounds and nucleic acid constituents. It has also been demonstrated spectroscopically that RNA/DNA nucleobases can bind to metal cations in aqueous solution through coordination bonds and covalent bonds. Nitrogen-15 NMR spectroscopy has been shown to be a useful tool for determining the mode of metal ion binding to nitrogen atoms in RNA/DNA molecules.

Introduction

Nitrogen combines with practically all other elements to form a myriad of inorganic and organic molecules. It is a key element present in all living organisms, in various compounds ranging from amino acids to proteins and from purines to nucleic acids. The nitrogen atom is also a crucial element in supramolecular chemistry and chemical biology. It is frequently a center of the intermolecular interactions (e.g., hydrogen bonds) which are responsible for chemical and physical properties and dictate the functional behavior of nanomaterials on one side and the biological functions of natural products and biomacromolecules on the other.

Intermolecular interactions change the molecular topology and the electron density around practically all of the atoms of the interacting systems, although the atoms on the interacting surfaces are usually affected most. The involvement of the lone pair of electrons on the nitrogen atom in these interactions is especially significant in modifying the spectral properties of ¹⁵N in the compounds investigated. Changes in the electron density induce changes in the nuclear shielding which can be advantageously determined and investigated by NMR spectroscopy. This makes NMR spectroscopy an invaluable tool for studying subtle changes in the distribution of electron density. As is apparent from the preceding paragraphs, the application of ¹⁵N NMR is not limited to structure-elucidation research, but is frequently applied in studies of the interactions between molecules and their environment. Interactions with the solvent and interactions inside of crystals have long been hot topics in structural chemistry.

Two NMR active nuclei, ¹⁴N and ¹⁵N, can be used for the above mentioned investigations. The ¹⁴N isotope is highly abundant in nature (99.64%), but its nuclear spin, $I=1$, leads to relatively broad NMR resonances (typically tens or hundreds of hertz). Despite its very low natural abundance (0.36%), the isotope ¹⁵N is preferred for

detection because of its suitable nuclear spin ($I=1/2$), which has been used in many routine polarization-transfer experiments. Various NMR parameters, for example, ¹⁵N chemical shifts, ¹H–¹⁵N coupling constants, and ¹⁵N relaxation times, are frequently employed in structural and dynamic studies of various phenomena such as tautomerism, protonation, complexation, hydrogen bonding, *N*-alkylation, and *N*-oxidation processes. Applications of ¹⁵N NMR in the structural characterization of organic and inorganic molecules are predominantly discussed in this contribution.

Referencing of Chemical Shifts

Referencing represents an important issue in ¹⁵N NMR spectroscopy for reasons to be discussed here. Unfortunately, there is no universally adopted reference standard or chemical shift scale in ¹⁵N NMR spectroscopy. The two most frequently used primary ¹⁵N standards are liquid ammonia (NH₃) and nitromethane (CH₃NO₂).

The highly shielded nitrogen resonance of ammonia gives an NMR chemical shift scale similar to those known for ¹H and ¹³C NMR spectroscopies, and the vast majority of nitrogen atoms in organic molecules and biomacromolecules are less shielded than that in ammonia. Their ¹⁵N resonances exhibit positive values for the chemical shift. Unfortunately, this standard is not easily prepared in routine practice, and its chemical shift depends upon the pH and temperature.

Due to its historical use and the ease of preparation, nitromethane is the second most frequently employed primary standard. Unfortunately, the position of the nitromethane nitrogen resonance typically produces negative (but sometimes positive) chemical shift values for the majority of organic compounds when it is used as a primary standard. This can be inconvenient for the analysis and discussion of the changes in the chemical shift.

Another standard is represented by a 1 mol l⁻¹ solution of urea in DMSO-*d*₆, which is very easy to prepare and is relatively insensitive to temperature changes. Other less frequently used standards are rather sensitive to changes in pH and variations in temperature, and they are therefore less suitable for routine standardization purposes. At this point, it should be noted explicitly that the ¹⁵N chemical shifts summarized in this review are reported relative to liquid ammonia, and positive values denote deshielding. The chemical shifts reported in the literature using different scales for the chemical shift

have been converted to this standard using the following values: liquid NH₃ (0.0 ppm), solid α -glycine (34.1 ppm), solid NH₄Cl (40.7 ppm), 1 mol l⁻¹ urea in DMSO (77.0 ppm), DMF (104.9 ppm), 1 mol l⁻¹ HNO₃ in H₂O (377.3 ppm), and liquid CH₃NO₂ (381.7 ppm).

For convenient preparation, stability, and ease of use of the resulting scale of chemical shifts, the following *secondary* external standards are recommended: (1) 1 mol l⁻¹ urea in DMSO-*d*₆ (77.0 ppm) or neat CH₃NO₂ (381.7 ppm) for NMR in solution and (2) powdered α -glycine (34.1 ppm) for solid-state studies.

The use of Ξ ratios allows the indirect referencing of ¹⁵N chemical shifts through direct referencing to a single, well-determined ¹H standard (e.g., TMS or DSS) and is frequently used in biological studies. Ξ ratios are independent of both the spectrometer design and the sample geometry and therefore, provide an accurate and consistent way to reference ¹⁵N chemical shifts.

Nuclear ¹H–¹⁵N Coupling Constants

The absolute values of the one-bond ¹H–¹⁵N coupling constants cover approximately the range 50–140 Hz, with values between 85 and 95 Hz being most common. These values are frequently used to optimize gradient-selected 2-D experiments (HSQC, HMQC) with the aim of determining directly bonded ¹H–¹⁵N pairs. Values of one-bond ¹H–¹⁵N coupling constants have often been used to characterize tautomeric equilibria.

The absolute values of multiple-bond (or long-range) ¹H–¹⁵N coupling constants cover the range 0–20 Hz. However, compromise values of the multiple-bond ¹H–¹⁵N couplings are used to adjust long-range heteronuclear shift correlation experiments (single-quantum or multiple-quantum variants) which nowadays are routinely used to elucidate structure. Knowledge of the multiple-bond ¹H–¹⁵N coupling constants (especially ³J_{H,N}) is very important for the interpretation because the Karplus dependence is frequently employed in stereochemical analysis.

¹⁵N Chemical Shifts

The combination of a large dispersion of chemical shifts – ~1000 ppm for organic molecules – and sensitivity to electronic interactions involving the lone pair of electrons has made the ¹⁵N chemical shift a very sensitive probe for both structural changes and intermolecular interactions. Methods of high-resolution NMR for measuring chemical shifts and indirect coupling constants in solution have been summarized in several recent review articles and will not be discussed here. Generally, inverse detection with gradient selection of the coherence pathway is the preferred tool for measuring ¹⁵N parameters because it is significantly more sensitive than direct detection.

However, sufficiently large indirect ¹H–¹⁵N coupling (approximately >0.5–1 Hz for small organic molecules) is essential for the successful application of techniques based on polarization transfer. The direct measurement of ¹⁵N NMR spectra remains the only possibility for nitrogens with vanishingly small indirect couplings to neighboring protons. **Table 1** shows the characteristic ranges of ¹⁵N chemical shifts (δ in ppm) in various types of compounds.

As compared to the isotropic chemical shift, however, the chemical shift tensor (CST), which describes the nuclear shielding in the three principal directions around the nucleus, is even more sensitive to all of the subtle changes in the electronic environment of the nitrogen nucleus. Full tensorial information – the principal components of the CST (eigenvalues) and the principal axes of the CST (eigenvectors) – is generally available only from single-crystal measurements or theoretical calculations (e.g., DFT). The principal components of the CST, however, can be obtained from measurements using powdered samples, although information about the principal orientations is not routinely available. Typically, the principal components of the ¹⁵N CST are labeled according to IUPAC rules: $\delta_{11} \geq \delta_{22} \geq \delta_{33}$. The anisotropy of the chemical shift can also be extracted from measurements of the chemical shifts and relaxation times found in anisotropic solutions (e.g., liquid crystals).

Nowadays, several approaches are available for obtaining the principal components of the CST for powdered samples. The most straightforward approach is represented by the analysis of the static solid-state powder pattern. The principal components can be measured directly from such a spectrum. However, a static spectrum suffers from two major disadvantages: low sensitivity and overlapping signals. Alternatively, the CST parameters can be determined by appropriate analysis of the spinning sideband patterns in slow-spinning CP/MAS spectra. When the MAS frequency is less than the chemical shift anisotropy, the isotropic line in the NMR spectrum is flanked on either side by sidebands spaced at the spinning frequency. The intensities of the spinning sidebands are related to the chemical shift anisotropy and thus provide a means to recover the CST parameters. The analysis of sideband patterns is relatively straightforward, but it cannot be applied to more complex molecules with crowded spectral regions. In such cases, more sophisticated techniques that separate isotropic and anisotropic interactions should be employed. The original 2-D experiments are currently being replaced by more complex techniques such as SPEED and FIREMAT.

The sensitivity of the ¹⁵N CST to structural change can be demonstrated by an example. Pyridine and pyrrole represent two principally different ¹⁵N CST in heterocyclic compounds (see **Figure 1**). The reported value of δ_{iso} for pyridine is 319 ppm, whereas that for pyrrole amounts to 149 ppm. This difference derives from altered

Table 1 Characteristic ranges of ¹⁵N chemical shifts (δ in ppm) in various types of compounds^a

Type of compound	δ_N (ppm)	Type of compound	δ_N (ppm)

contributions by all three of the principal components. δ_{33} is the least altered component ($\Delta\delta \sim 100$ ppm) and is oriented perpendicular to the heterocyclic skeleton for both compounds. Depending on the type of nitrogen, either δ_{11} (pyridine) or δ_{22} (pyrrole) assumes an approximately tangential orientation (δ_t) with respect to the heterocyclic skeleton, and the remaining component is consequently found with an approximately radial orientation (δ_r). The radial component is labeled δ_{22} for pyridine and δ_{11} for pyrrole. For the two compounds, the resultant difference $\Delta\delta_r$ is ~ 170 ppm. (see **Figure 1**). The component most sensitive to the difference in the type of bonding at the nitrogen atom is the one tangential to the ring system. The difference between the values of the tangential components of the ¹⁵N CST of pyridine and

pyrrole is more than 430 ppm. Although the changes in the chemical shift of ¹⁵N associated with protonation, complexation, and hydrogen bonding (to be discussed later) are much smaller, tensorial properties are very sensitive indicators for all of these processes. **Table 2** represents the experimental principal components of the ¹⁵N CST in selected heterocyclic compounds.

Interatomic Distances

Techniques for measuring the N–H bond length in the solid-state are typically based on measuring the dipole–dipole coupling ($D_{H,N}$) followed by calculating the effective internuclear distance ($r_{H,N}^{\text{eff}}$) as

$$r_{H,N}^{\text{eff}} = \sqrt[3]{\left| \frac{\mu_0 \hbar \gamma_H \gamma_N}{4\pi D_{H,N}} \right|} \quad (1)$$

The effective $D_{H,N}$ can currently be measured precisely enough to determine short N–H bond distances with an accuracy of 1–2 pm. The fact that the measured N–H distances are actually somewhat longer (usually 1–3 pm) than the equilibrium distances determined by neutron diffraction and calculated by standard methods of quantum chemistry is due to nuclear motion. This motion must therefore be taken into account when interpreting the experimentally determined dipolar coupling constants. To a close approximation, the dependence of $r_{H,N}^{-3}$ is governed by the stretching vibration along the H–N bond

Table 2 Experimental principal components of the ¹⁵N CST in heterocyclic compounds

Heterocyclic compounds	Atom	δ_{iso}	δ_{11}	δ_{22}	δ_{33}

(lowering the $D_{H,N}$ by approximately 1.5%) and bending motions involving the perpetual reorientation of the H–N bond vector (reducing the $D_{H,N}$ by approximately 7%). Solid-state ¹H–¹⁵N correlation experiments employing ¹H detection under fast MAS conditions currently provide a substantial gain in signal sensitivity and allow for the precise determination of N–H bond lengths for samples with ¹⁵N at natural abundance. The dipole–dipole coupling constants can be extracted from 2-D recoupling experiments or from the spinning sideband patterns generated by recently developed recoupling strategies.

Relaxation and Dynamics

The ¹H–¹⁵N pair is frequently employed as a probe for relaxation measurements of peptides, proteins, and nucleic acids. The dynamics of the system is subsequently evaluated from these relaxation measurements using currently available approaches (e.g., the model-free approach and the slowly relaxing local structure approach). More extensive descriptions of the relaxation phenomena are presented in other articles of this encyclopedia.

Theoretical Calculations

Several books and review articles have been devoted to the detailed description of the theory behind the calculation of nuclear shielding tensors and indirect spin–spin coupling constants, and many applications can be found in the older as well as the more recent literature. The combined experimental and theoretical approaches represent an extremely rapidly expanding field of ¹⁵N NMR structural analysis. This short paragraph makes no attempt to discuss theoretical calculations, but an important point is worth mentioning.

As discussed previously, ¹⁵N chemical shifts are extremely sensitive to intermolecular interactions. Thus the

inclusion of the environment of the molecule being investigated is essential for any calculations involving ¹⁵N. However, the intermolecular interactions must also be incorporated in calculations done for the reference that is subsequently used to convert the nuclear shielding to the chemical shift. The intermolecular interactions can be simulated by explicit or implicit solvent models for solution-state NMR and by including the neighboring molecules (cluster approach) or the periodic boundary conditions from crystal packing for solid-state NMR.

If a secondary standard is used as a reference, in accordance with the experimental standardization procedures (see section ‘Referencing of Chemical Shifts’), the chemical shift can be calculated by using the following equation: $\delta_{\text{sample}} = \sigma_{\text{ref}} - \sigma_{\text{sample}} + \delta_{\text{ref}}$. In this equation δ_{ref} and σ_{ref} are the experimental chemical shift and the computed isotropic nuclear shielding, respectively, of a suitable secondary reference standard.

Applications

Phenomena involving the lone pair of electrons of the nitrogen atom can be advantageously investigated by ¹⁵N NMR spectroscopy. Processes such as hydrogen bonding, protonation, complexation, and alkylation at a pyridine-type of nitrogen diminish the deshielding contribution of the lone pair of electrons, resulting in greater total shielding. The magnitude of this shielding effect ranges from several parts per million for hydrogen bonding and other intermolecular interactions to more than 100 ppm when a covalent or complex bond is formed in a process such as alkylation, protonation, or metal complexation. In contrast, the trapping of the protons of the N–H groups in hydrogen bonding induces a remarkably large deshielding of the nitrogen nucleus. Although a number of chemical

processes affecting the nitrogen atom can be investigated by ¹⁵N NMR, only a very few typical examples are presented in the following sections, and the interested reader is referred to the more comprehensive application reviews listed in the section 'Further Reading.'

Regioisomerism

As demonstrated for the CSTs of pyridine and pyrrole, the difference in isotropic chemical shift between –N= and –NR– types of nitrogen atoms amount to approximately 100 ppm. This difference can be used advantageously to investigate regioisomers by using inverse-detected long-range ¹H–¹⁵N chemical shift correlation experiments in solution. The long-range interactions of the nitrogen atom with protons separated by two to four bonds can help significantly in unambiguously assigning alkyl or aryl substituents to a particular nitrogen site. The long-range ¹H–¹⁵N coupling pathways detected are also used as a new type of restraint in computer programs designed to automatically elucidate the structure of a compound. An example of regioisomerism in purines and its effect on the ¹⁵N parameters is shown in **Figure 2**.

Configuration at the C=N Bond

The magnitudes of two-bond ¹H–¹⁵N and ¹³C–¹⁵N coupling constants are significantly affected by the stereochemical orientation of the hydrogen or carbon atom relative to the lone pair of electrons on the nitrogen. Examples of the ²J_{H,N} and ²J_{C,N} coupling constants are shown in **Figure 3**. The values of the coupling constants differ considerably for a planar arrangement and are little affected by the character of the substituents in this type of

Figure 2 ¹⁵N chemical shifts and ¹H–¹⁵N coupling constants in N-7- and N-9-methyl purine. Adapted from Marek R and Sklenář V (2005) NMR studies of purines. *Annual Reports on NMR Spectroscopy* 54: 201, Figure 10, with permission.

compound. Both ²J_{H,N} and ²J_{C,N} coupling constants have frequently been employed to investigate *E/Z* isomerism.

Tautomerism

Various forms of tautomerism are common in nitrogen containing compounds, and a plethora of papers on this topic therefore exists. Both ¹⁵N chemical shifts and ¹J_{H,N} coupling constants can be used to evaluate tautomeric equilibria quantitatively. One of the most obvious examples is represented by azo–hydrazone tautomerism. The ¹⁵N chemical shift of the representative aromatic azo group is 450 ppm (**Figure 4**). The transfer of a proton from the OH group to the nitrogen atom and the rearrangement of the electrons in the conjugated system induce shielding of the –NH– nitrogen atom by ~275 ppm. The corresponding ¹H–¹⁵N coupling constant amounts to approximately 96 Hz. However, only one set of signals is observed if the azo–hydrazone exchange process is fast on an NMR time scale. The populations of the individual contributors can be determined from the time-averaged values of δ_N and J_{H,N}, which represent the population-weighted contributions of the two forms. Other examples are tautomerism of azoles, purines, porphyrins, benzamidines, and Schiff bases; tetrazole–azide tautomerism; and thio-cyanatoacetophenone–4-arylthiazolone tautomerism. Experimental studies are frequently complemented by quantum chemical calculations.

Figure 3 Stereochemical dependence of two-bond ¹H–¹⁵N and ¹³C–¹⁵N coupling constants for a C=N moiety.

Figure 4 Effect of azo–hydrazone tautomerism on the ¹⁵N NMR parameters.

Protonation

The nitrogen nucleus has proven to be suitable for expressing the changes between the different hybridization states resulting from protonation. The behavior of the nitrogen resonance during the protonation process is very similar to that described for the contrast between pyridine and pyrrole. Protonation induces a change in the nitrogen resonance from 319 ppm for pyridine to 213 ppm for pyridinium ion. This change too occurs mainly in the component oriented approximately tangential to the aromatic ring (δ_t : 582 $\rightarrow$ 285; δ_r : 415 $\rightarrow$ 352; $\delta_\perp$: -40 $\rightarrow$ 1). The ¹⁵N CSTs for pyridine and for pyridinium ion are shown in Figure 5.

Metal Complexation

The observed shielding effect on the -N= type of nitrogen atom (e.g., that of pyridine) induced by metal complexation results from the removal of the deshielding contribution of the lone pair of electrons. This is clearly analogous to protonation and alkylation processes, although the contribution of the metal in this case must not be overlooked. The contribution of the metal to the chemical shift of a neighboring nitrogen atom can be substantial, especially for heavy atoms (e.g., Pt and Hg). The complexation shielding effect for the pyridine-type of nitrogen typically ranges from several tens to more than 100 ppm. For example, complexation of N-6-benzylamino purine derivatives via the N-7 atom increases the N-7 shielding by approximately 107 ppm (see Figure 6). In contrast, nitrogens N-1, N-9, and NH are slightly deshielded by the complexation process, probably due to changes in electron density around the aromatic system.

Hydrogen Bonding

Hydrogen bonding studies in solution (common deuterated solvents or mixtures of different freons) frequently require low-temperature measurements to slow the exchange rates of any processes involving proton transfer. The nature of the hydrogen bonds can be assessed by

Figure 5 Effect of protonation on the ¹⁵N CST of pyridine (δ in ppm): pyridine and pyridinium ion.

using ¹H and ¹⁵N chemical shifts and indirect ¹H-¹⁵N coupling constants. An example demonstrating the magnitude of the shielding for -N= and the deshielding for -NH- is shown in Figure 7.

Figure 6 Changes in the ¹⁵N NMR chemical shifts (δ in ppm) of N-6-benzylamino purines induced by complexation with PtCl₂.

Figure 7 Hydrogen bonding effect on the ¹⁵N CST of HB donor and acceptor atoms.

Figure 8 Schematic representation of the resonance assisted tautomerism and hydrogen bonding of some Schiff bases.

An interesting phenomenon involving the nitrogen atom is the so-called ‘resonance-assisted hydrogen bonding’ (e.g., **Figure 8**). The shape of the potential for the proton transfer can be advantageously investigated using ¹⁵N NMR spectroscopy and measuring the deuterium isotope effect on the ¹⁵N parameters.

Measurements of dipolar ¹H–¹⁵N coupling constants in the solid-state offer the opportunity to determine not only the N–H bond lengths but also the relatively long interatomic distances between different molecules. These intermolecular separations are governed indirectly by the strength of intermolecular attractive forces, such as hydrogen bonding, which can be investigated by the ¹⁵N NMR. HB interactions of the N–H–N type can be further studied by using ²*J*_{N,N} coupling constants across hydrogen bonds. In addition, the dynamics of proton motion in N–H groups and proton jumps between two different sites can be investigated using relaxation measurements.

Perspectives

¹⁵N NMR represents a surprisingly dynamically developing branch of NMR spectroscopy capable of offering new and versatile data in many branches of science. As demonstrated in the preceding sections, the reasons for this dynamic development arise from the enormous potential for structural studies of intermolecular interactions and for applications in supramolecular and biological chemistry. The combined experimental and theoretical approaches represent an extremely rapidly expanding field of ¹⁵N structural analysis. Applications of the combined approaches are providing unprecedented details about the electronic structures of molecular systems, supramolecular topology, and the dynamics of molecular and supramolecular units.

Symbols

$C_{ix_s}(e)$	trigonometric factors, (e) refers to extraordinary ray
E	electric field strength of incident radiation
$I(\omega)$	intensity of incident/scattered radiation
i, j, k	coordinate system of crystal
k_i	wave vector of beam i
L_{ijk}	local-field correction
n	order of nonlinear effect
n_i	refractive index of medium at ω_i
(o)	refers to the ordinary ray
$p^{(n)}$	molecular induced electric dipole moment (n th-order effect)
$P^{(1)}$	volume polarization
V	volume of unit cell
x_s, y_s, z_s	coordinate system of molecules
$\alpha^{(n)}$	molecular polarizability of n th order
δ_{ijk}	Miller index
ϵ_0	permittivity of free space
λ	wavelength
μ	static molecular dipole moment
ϕ	phase angle
$\chi^{(1)}$	macroscopic susceptibility
$\chi_s^{(2)}$	surface susceptibility
ω	photon frequency

Nonlinear optical phenomena manifest themselves as special forms of light scattering and refraction. Ordinary, linear, light scattering may be viewed as a quasi-simultaneous absorption and re-emission of a photon of same frequency ω . The event occurs on a very short timescale; for radiation in the UV-visible region, of the order of 10^{-15} s, or 1 fs. Light scattering is not to be confounded with resonant absorption and emission. Atoms and molecules absorb and emit light at particular, selected frequencies; they scatter light within the whole spectrum of electromagnetic radiation. Resonant absorption and emission are connected with a change of energy state of the atom or molecule; light scattering is an elastic process, leaving the atom or molecule in the same state after as before the event. Under conditions that will be specified in more detail below, forms of elastic scattering may also occur in which more than one incident photon

are involved. For instance, it may happen that two photons of frequency ω incident on a molecule merge to form a single re-emitted photon of frequency 2ω . This process is called second-harmonic generation and is a nonlinear optical phenomenon.

In the following, the most important nonlinear optical effects are reviewed. The emphasis is laid on the material systems in which they have been observed. Nonlinear optical properties of both organic and inorganic materials are presented in tabular form and commented on.

Basic Quantities

The semiclassical description of light scattering attributes the effect to a light-induced (electric) dipole moment $p^{(1)}$ in the molecule that oscillates with the frequency of the incident radiation ω and becomes the source of quasi-immediate re-emission at the same frequency. Mathematically, this is expressed as

$$P^{(1)}(\omega) = \alpha^{(1)}(-\omega; \omega) \cdot E(\omega) \quad [1a]$$

$E(\omega)$ is the electric field strength of the incident light at the frequency ω , and $\alpha^{(1)}(-\omega; \omega)$ the molecular frequency-dependent polarizability of first order. The descriptive parenthesis $(-\omega; \omega)$ indicates incidence at frequency ω and quasi-simultaneous re-emission at frequency ω . For a macroscopic sample we have the corresponding equation:

$$P^{(1)}(\omega) = \epsilon_0 \chi^{(1)}(-\omega; \omega) \cdot E(\omega) \quad [1b]$$

where $P^{(1)}(\omega)$ is the volume polarization and $\chi^{(1)}(-\omega; \omega)$ the macroscopic susceptibility. χ is the appropriate sum of the molecular contributions α .

If two separate radiation frequencies, ω_1 and ω_2 , act on a molecule at the same time, we will mainly have separate and distinct scattering at these two basic frequencies. However, if the coherence and intensity of the incident radiation are sufficiently high, we may observe the generation of 'overtones' of frequency $\omega_1 + \omega_2$:

$$P^{(2)}(\omega_1 + \omega_2) = \alpha^{(2)}(-\omega_1 - \omega_2; \omega_1, \omega_2) : {}^1E(\omega_1)^2 E(\omega_2) \quad [2]$$

We notice that the induced polarization $P^{(2)}$ for this second-order effect is proportional to the product of

the field strengths ${}^1E(\omega_1)$ and ${}^2E(\omega_2)$. The parenthesis $(-\omega_1 - \omega_2; \omega_1, \omega_2)$ indicates incidence at frequencies ω_1 and ω_2 and scattering at frequency $\omega_1 + \omega_2$.

For $\omega_1 = \omega_2$, sum-frequency generation becomes tantamount to second-harmonic generation (SHG), i.e. incidence at frequency ω and quasi-simultaneous re-emission at the doubled frequency 2ω :

$$P^{(2)}(2\omega) = \alpha^{(2)}(-2\omega; \omega, \omega) : E^2(\omega) \quad [3]$$

We encounter a situation for which the induced polarization is no longer linearly but now quadratically dependent on the field strength of the incident radiation. Correspondingly, the intensity of the radiation generated at frequency 2ω is also quadratically dependent on the intensity $I(\omega)$. In contrast, the intensity of 'ordinary' light scattering at frequency ω is linearly dependent on $I(\omega)$.

As well as sum-frequency generation, the nonlinear optical effect of difference frequency generation is also possible, $\omega_1 - \omega_2$ being generated from ω_1 and ω_2 . For $\omega_1 = \omega_2$, we then have optical rectification, namely, the induction of a static electric polarization of frequency 0, by the radiation field:

$$P^{(2)}(0) = \alpha^{(2)}(0; \omega, -\omega) : {}^1E(\omega) {}^2E(-\omega) \quad [4]$$

(Mathematically, $E(-\omega)$ is expressed as the complex conjugate of $E(\omega)$.)

Tables 1 and 2 and Figure 1 summarize a number of distinct nonlinear optical effects, in particular including those of third order arising from the combined influence of three frequencies, $\omega_1, \omega_2, \omega_3$. These effects are collectively called four-wave mixing, as three incident waves combine coherently to give a fourth resulting in one of frequency $\omega_1 \pm \omega_2 \pm \omega_3$. The radiation-induced polarization depends to third order on the electric field strength of the incident radiation, namely, on the triple product ${}^1E(\omega_1) {}^2E(\pm\omega_2) {}^3E(\pm\omega_3)$. In the particular case where $\omega_1 = \omega_2 = \omega_3$, we may have third-harmonic generation, proportional to $E^3(\omega)$. Correspondingly, the

intensity of the third harmonic radiation $I(3\omega)$ depends on $I^3(\omega)$.

The variety of nonlinear optical phenomena is indeed vast, but with increasing order their observation becomes more and more difficult. Conventional, thermal light sources do not produce radiation of sufficient coherence and intensity to induce observable nonlinear effects. The field of nonlinear optics has been made accessible by the laser. Laser light is generated by induced emission and can be pictured as consisting of wave trains oscillating in phase. This allows the generation of tightly bundled, sharply focusable beams of high intensity.

The key quantity to understanding the nonlinear optical response of a given molecule is the corresponding generalized polarizability $\alpha^{(n)}(\dots)$, sometimes also called molecular susceptibility or, for $n > 1$, hyperpolarizability, where n denotes the order of the effect. The first-order polarizability $\alpha^{(1)}$ is a second-rank tensor. The tensor is symmetric and, therefore, in general has six independent elements, assumed to be defined in a symmetry-adapted molecular reference frame x, y, z . These six different tensor elements manifest themselves in point groups belonging to the triclinic symmetry system: $xx(\equiv\alpha_{xx}^{(1)}), yy, zz, xy=yx, yz=zy, zx=xz$. In the monoclinic system, there occur four independent elements. In higher systems, by symmetry the tensor becomes diagonal. In the cubic system, all three diagonal elements are the same. For an isotropic medium, we obtain a single scalar average.

The second-order polarizabilities $\alpha^{(2)}(\dots)$ are third-rank tensors. Such tensors in general vanish in centrosymmetric media, as they are parity-odd. In the triclinic symmetry system, there are $3^3 = 27$ independent tensor elements. In a molecule of higher symmetry, some elements become zero, others may be equal to each other (see **Table 3**). For instance, in the chiral cubic point group O , the only nonvanishing elements are: $xyz = yzx = zxy = -xzy = -yxz = -zyx$; in the achiral point group T_d : $xyz = yzx = zxy = xzy = yxz = zyx$. For these cases, a second-order nonlinear response can only

Table 1 Overall classification of nonlinear optical effects

Frequency of incident radiation	Frequency of scattered radiation	Order of effect (n)	Rank of susceptibility tensor	Name/description
ω	ω	1	2	Rayleigh scattering Ordinary refraction
ω_1, ω_2	$\omega_1 + \omega_2$ $\omega_1 - \omega_2$	2	3	Sum-frequency generation Difference-frequency generation
$\omega_1, \omega_2, \omega_3$	$\omega_1 + \omega_2 + \omega_3$ $\omega_1 + \omega_2 - \omega_3$ $\omega_1 - \omega_2 + \omega_3$ $\omega_1 - \omega_2 - \omega_3$	3	4	Four-wave mixing
$\omega_1, \omega_2, \omega_3, \omega_4$	$\omega_1 \pm \omega_2 \pm \omega_3 \pm \omega_4$	4	5	Five-wave mixing

Table 2 Some important nonlinear optical effects

Frequencies of interacting electric fields	Effect	First experiment
$\omega + \omega \rightarrow 2\omega$	Second-harmonic generation (SHG)	<i>a</i>
$\omega - \omega \rightarrow 0$	Optical rectification (OR)	<i>b</i>
$2\omega - \omega \rightarrow \omega$	Parametric amplification (PA)	<i>c</i>

be detected if 1E and 2E are nonparallel to one and the same symmetry-adapted coordinate axis. As will be seen in more detail in the next section, in an isotropic medium, the averaged value of $\alpha^{(2)}$ only fails to vanish if the individual molecules of which the medium is composed are chiral, and if the frequencies ω_1 and ω_2 of the incident radiation are different.

The third-order polarizabilities $\alpha^{(3)}$ (...) are parity-even fourth-rank tensors. In the triclinic system, there occur $3^4 = 81$ independent and nonzero tensor elements. The presence of symmetry leads to corresponding simplifications.

The same symmetry considerations, which here are stated for individual molecules, may of course also be applied to macroscopic systems, in particular to crystals. The determining aspect is here the overall crystal symmetry, and instead of the molecular polarizabilities $\alpha^{(n)}$, we consider the bulk susceptibilities of the crystal $\chi^{(n)}$.

Organic Media

Organic Liquids and Solutions

The nonlinear optical properties of solutions of organic molecules have been investigated extensively, although the selection rules for second-order nonlinear optical effects in isotropic liquids are quite restrictive. In order to be noncentrosymmetric, a fluid must consist of, or contain, chiral molecules. Such a chiral medium is 'optically active' and not superposable on its mirror image. Although sum and difference frequency generation are then possible, the important special cases of second-harmonic generation and optical rectification are still forbidden. The respective molecular polarizabilities $\alpha^{(2)}(-2\omega; \omega, \omega)$ and $\alpha^{(2)}(0; \omega, -\omega)$ vanish upon isotropic averaging.

Second-harmonic generation may be induced in any liquid medium (or gas) if an external static electric field is applied to it, whereby the medium loses its centrosymmetry and the conditions for second-harmonic generation are fulfilled. The generalized polarizability

leading to this effect may be expressed as $\alpha^{(3)}(-2\omega; \omega, \omega, 0)$ and is described by a fourth-rank tensor. With electric field strengths applicable in the laboratory, the effect is in general quite small. However, if the liquid is composed of polar molecules (not necessarily chiral), the applied electric field will also partially align them. This then leads to an additional, temperature-dependent, contribution to second-harmonic generation that can be stronger. It is proportional to the molecular dipole moment μ and to an average value of the tensor $\alpha^{(2)}(-2\omega; \omega, \omega)$, often denoted in the literature by β . Electric field-induced second-harmonic generation, in the literature sometimes abbreviated as EFISH, has been widely applied to study solutions of polar organic molecules in nonpolar solvents. To allow extraction of significant molecular data, the interaction between solute molecules should be negligible and the influence of the nonpolar solvent must be taken into account as an averaged correction.

Although second-harmonic generation attained by the EFISH effect is in general weak, the method has been applied widely and successfully. The molecular data so obtained serve as a point of departure for the interpretation of the nonlinear optical properties of molecular crystals and arrays and for the design of novel systems. One observes (see **Table 4** and **Table 5**) that particularly large quantities for β are found in molecules containing one or more electron-donor substituent(s), such as $-\text{NH}_2$ (amino), one or more electron-acceptor substituent(s), such as $-\text{NO}_2$ (nitro), bound to a polarizable π electron system (containing conjugated $\text{C}=\text{C}$ double bonds).

The tensor elements of the molecular quantity $\alpha^{(2)}(-2\omega; \omega, \omega)$ and, therefrom, the averaged quantity β may in principle be calculated quantum mechanically. $\alpha^{(2)}$ may be expressed in terms of the energy levels of the molecule and the electric dipole transition moments between the corresponding quantum states. Exact (*ab initio*) calculations are very cumbersome, but a number of simplified procedures (semiempirical calculations) have been applied to this problem and their results allow a reasonably successful interpretation of the measured

Figure 1 Ward graphs (at left) and ladder graphs (at right) for linear (S2.a), second-order nonlinear (S3.a, b), and third-order nonlinear (S4.a, b1, b2) elastic scattering processes. The broken horizontal lines in the ladder graphs represent virtual, nonstationary states of the molecular system. results, in particular where strong charge-transfer effects come into play.

Third-order nonlinear optical effects, such as third-harmonic generation or other kinds of four-wave mixing phenomena, occur in all media, irrespective of their symmetry. This follows from the parity-even property of the corresponding tensors. Consequently, third-harmonic generation can be observed in both liquids and gases. Some results on organic molecules are given in **Table 4** and **Table 5**. In general γ , the dominant component of $\alpha^{(3)}(-3\omega; \omega, \omega, \omega)$, is a small quantity leading to correspondingly small effects.

Organic Layers and Crystals

Any surface or interface breaks the inversion symmetry and is therefore a possible source of second-order effects. Owing to their surface sensitivity, second-harmonic generation measurements have developed into a very useful tool for probing the orientation of organic molecules in well-structured monolayers, such as those obtainable by the Langmuir–Blodgett technique (see **Table 6**). The surface susceptibility may in general be written as

$$\chi_S^{(2)} = \chi_{SM}^{(2)} + \chi_{SB}^{(2)} \quad [5a]$$

where $\chi_{SM}^{(2)}$ stands for the part arising from the adsorbed molecules and $\chi_{SB}^{(2)}$ for the background contribution of the adjoining media. In order to obtain strong signals, the molecules in the layer must themselves be non-centrosymmetric. Often one chooses the adjoining bulk media to be centrosymmetric (air, water, glass; see

Figure 2). Then

$$\chi_S^{(2)} \approx \chi_{SM}^{(2)} \quad \chi_{SM}^{(2)} \gg \chi_{SB}^{(2)} \quad [5b]$$

Among organic crystals, one of the most frequently used for second-harmonic generation is urea, composed of noncentrosymmetric molecules arranged in a non-centrosymmetric fashion, according to the tetragonal space group $P4_21m = D_{2d}^3$ (see **Table 7**). Much attention has been devoted to the design and fabrication of even more efficient media, based on large β values obtained from EFISH experiments. In some cases, such as that of *p*-nitroaniline, β is large, but the molecules crystallize in a centrosymmetric space group, rendering the crystal useless. One strategy to overcome such difficulties consists in making the molecules chiral, thereby forcing them into a noncentrosymmetric crystal structure. From a theoretical point of view, one is interested in relating the bulk susceptibility of the crystal $\chi_{ijk}^{(2)}$ to the polarisabilities of the individual molecules $\alpha_{xyz}^{(2)}$ in their respective positions and orientations in the unit cell. Neglecting intermolecular interaction, this may be written as a sum

$$\chi_{ijk}^{(2)} = \frac{1}{V} L_{ijk} \sum_s \sum_{x_s, y_s, z_s} C_{ix_s} C_{jy_s} C_{kz_s} \alpha_{x_s y_s z_s}^{(2)} \quad [6]$$

where i, j, k denote the coordinate system of the crystal, x_s, y_s, z_s that of the molecule s in the unit cell. L_{ijk} is a local-field correction, V the volume of the unit cell. The trigonometric factors C_{ix_s} relate the molecular coordinate system to that of the crystal. This purely

additive orientated gas model presents a useful first approximation for the interpretation of data on organic molecules. To refine it, intermolecular interaction in the crystal must be included in the calculation. For crystals of strongly polar molecules, methods based on the dipole-dipole approximation have been successful.

From Harmonic Generation to Parametric Amplification

Conservation of Photon Energy

The photons involved in a nonlinear optical process must fulfil the requirement of energy conservation. For a

three-wave mixing effect in which the incident photons are of frequency ω_1, ω_2 , leading to an outgoing photon of frequency ω_3 , this implies

$$\omega_1 + \omega_2 = \omega_3 \quad [7]$$

For sum-frequency generation, where $\omega_3 = (\omega_1 + \omega_2)$, this is automatically fulfilled. For difference-frequency generation, where $\omega_3 = (\omega_1 - \omega_2)$, the above equation as such evidently cannot be satisfied; we must write

$$\omega_1 + \omega_2 = \omega_3 + 2\omega_2 \quad [8]$$

This means that for each incident photon of frequency ω_2 there are two outgoing photons of the same frequency. Simultaneously with the generation of a new wave of frequency $\omega_1 - \omega_2$, the incident wave of frequency ω_2 is parametrically amplified. If the nonlinear medium is placed between two mirrors reflecting at the frequencies ω_2 and (or) ω_3 , this parametric effect may be increased. One calls such a device a parametric oscillator (see **Figure 3**). From this point of view, $\omega_1 \equiv \omega_p$ corresponds to the so-called pump wave, $\omega_2 \equiv \omega_s$ to the (amplified) signal wave, and $\omega_3 \equiv (\omega_1 - \omega_2) \equiv \omega_i$ to the idler wave. Equation [8] may be simplified to

$$\omega_1 = \omega_2 + \omega_3 \text{ or } \omega_p = \omega_s + \omega_i \quad [9]$$

The fundamental process then appears to be the conversion of a photon of higher frequency ω_p into two photons of lower frequency ω_s and ω_i . Interestingly, this process may go on in a parametric oscillator merely as a result of sending in a pump wave. The signal photons are first generated inside the cavity by spontaneous emission and then coherently amplified. Carried out in this manner, the intensity of the signal wave becomes linearly dependent on the intensity of the incident pump wave.

(I) For type I phase-matched SHG; (II) for type II phase-matched SHG.

**Figure 3** Schematic representation of a singly-resonant optical parametric oscillator. Pump wave of frequency ω_P , (reflected) signal wave of frequency ω_S , idler wave of frequency ω_I . The signal wave ω_S becomes amplified. θ_P denotes the angle of orientation of the direction of propagation with respect to the crystal optic axis. Adapted with permission from Tang CL and Cheng LK (1995) *Fundamentals of Optical Parametric Processes and Oscillators*. Amsterdam: Harwood Academic Publishers.

Evidently, a photon of frequency ω_P may break up into two photons of lower frequency in an infinity of ways, depending on the relative frequencies ω_S and ω_I . In

order to select which frequency ω_S should be amplified, the parametric oscillator must be correspondingly tuned. The most important and practical way to achieve this tuning is by phase matching in a crystal.

Conservation of Photon Momentum: Phase Matching

To optimize the intensity of a coherent nonlinear optical effect, there must be conservation of photon momentum. For sum-frequency generation this requirement is expressed as

$$\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_3 \quad [10a]$$

$\mathbf{k}_i$ denotes the wave vector of the corresponding beam. To avoid reduction of effective beam interaction length due to finite cross sections, collinear phase matching is aimed

at. One then may write eqn [10a] in scalar form

$$k_1 + k_2 = k_3 \quad [10b]$$

With $k_i = n_i 2\pi / \lambda_i$, where $n_i \equiv n(\omega_i)$ stands for the refractive index of the medium at frequency ω_i and λ_i for the vacuum wavelength, this may be expressed as

$$\omega_1 n_1 + \omega_2 n_2 = \omega_3 n_3 \quad [10c]$$

In a lossless medium, $n(\omega)$ in general increases monotonically with ω owing to normal dispersion. In an isotropic medium such as a liquid, $n(\omega)$ is independent of beam polarization. It can then easily be shown that for $\omega_1 \leq \omega_2 < \omega_3$, eqn [10c] cannot be satisfied.

In a uniaxial birefringent crystal, excluding propagation along the optic axis, an incident beam may, depending on its polarization, be made ordinary or extraordinary. The ordinary (o) and extraordinary (e) rays, perpendicularly polarized with respect to each other, will each experience a different index of refraction, $n^{(o)}(\omega) \neq n^{(e)}(\omega)$. According to the crystalline medium, the frequency ω and the angle of incidence with respect to the optic axis, situations may be found where the phase-matching condition is fulfilled.

For sum-frequency generation in a positive uniaxial crystal, in which $n^{(e)} > n^{(o)}$, the phase-matching condition may be satisfied in two different ways:

$$\begin{aligned} n_1^{(e)} \omega_1 + n_2^{(e)} \omega_2 &= n_3^{(o)} \omega_3 \text{ Type I} \\ n_1^{(o)} \omega_1 + n_2^{(e)} \omega_2 &= n_3^{(o)} \omega_3 \text{ Type II} \end{aligned} \quad [11a]$$

or

$$n_1^{(e)} \omega_1 + n_2^{(o)} \omega_2 = n_3^{(o)} \omega_3 \quad [11b]$$

Similarly for the parametric effect in a negative uniaxial crystal, in which $n^{(e)} < n^{(o)}$ (see **Figure 4**):

$$\begin{aligned} n_p^{(e)} \omega_p &= n_s^{(o)} \omega_s + n_i^{(o)} \omega_i \text{ Type I} \\ n_p^{(e)} \omega_p &= n_s^{(e)} \omega_s + n_i^{(o)} \omega_i \text{ Type II} \end{aligned} \quad [12a]$$

or

$$n_p^{(e)} \omega_p = n_s^{(o)} \omega_s + n_i^{(e)} \omega_i \quad [12b]$$

Crystals belonging to the cubic crystal system are isotropic, and therefore unsuited for phase-matching. Tetragonal and trigonal crystals are uniaxial; those of the orthorhombic, monoclinic and triclinic symmetry are biaxial. The description of phase-matching in biaxial

Figure 4 Phase-matching in an optical parametric process to achieve photon momentum conservation is based on the use of birefringence to compensate for normal material dispersion. In a uniaxial crystal, the ordinary wave (o) is polarized perpendicularly to the plane defined by the direction of propagation and the optic axis. The corresponding value of $k^{(o)}$ (or $n^{(o)}$) is independent of θ_p , the angle of orientation of the direction of propagation with respect to the optic axis. $k_s^{(o)}$ and $k_i^{(o)}$ therefore lie on a circle. The extraordinary wave (e) is polarized in the plane defined by the direction of propagation and the optic axis. The value of $k_p^{(e)}$ (or $n_p^{(e)}$) in its dependence on θ_p is described by an ellipse. In a negative uniaxial crystal, and for given values of $\omega_p = \omega_s + \omega_i$, the ellipse for $k_p^{(e)}$ may intersect the circle for $k_s^{(o)} + k_i^{(o)}$. At the corresponding angle θ_p , there is phase-matching. Rotation of the crystal relative to the direction of propagation of the waves correspondingly leads to tuning of the frequencies of the signal and idler waves. Adapted with permission from Tang CL and Cheng LK (1995). *Fundamentals of Optical Parametric Processes and Oscillators*. Amsterdam: Harwood Academic Publishers.

crystals is somewhat more complicated than in uniaxial crystals, but it essentially rests on the same principles.

The search for birefringent crystals with good phase-matching properties is of great technical importance in nonlinear optics. Although phase-matching has been achieved in organic crystals (see **Table 7**), inorganic materials appear so far to offer a greater variety of possibilities.

Inorganic Media

Noncentrosymmetric Crystals

Inorganic crystals are widely applied for second-harmonic generation and for optical parametric processes. Some frequently used materials: for second-harmonic

generation from the near-IR into the visible and beyond KH_2PO_4 (KDP), KD_2PO_4 (KD*P) and more recently $\beta\text{-BaB}_2\text{O}_4$ (BBO). For optical parametric amplification into the mid-IR: AgGaSe_2 , GaSe ; the visible and near-IR: LiNbO_3 , KTiOPO_4 , KNbO_3 ; and into the visible and UV: $\beta\text{-BaB}_2\text{O}_4$ and LiB_3O_5 .

Table 8 shows experimental second-order nonlinear optical susceptibilities for different tensor components d_{ij} and various fundamental wavelengths. The quantities d_{ij} are defined as follows:

$$\chi_{ijk}^{(2)}(2\omega) = 2d_{ijk}(2\omega) \quad [13]$$

The second and third indices of d_{ijk} are then replaced by a single symbol l according to the piezoelectric contraction:

jk :	11	22	33	23,32	31,13	12,21
k :	1	2	3	4	5	6

The nonlinear susceptibility tensor can then be represented as a 3×6 matrix containing 18 elements. In the transparent region, i.e. outside of absorption bands, one may assume the validity of the Kleinman symmetry condition, which states that the indices i, j, k may be freely permuted:

$$d_{ijk} = d_{kij} = d_{jki}, \text{ etc.} \quad [14a]$$

One then finds, for instance,

$$d_{123} = d_{321}, \quad d_{14} = d_{36} \quad [14b]$$

In this case there are only 10 independent elements for d_{ij} .

Table 8 shows that the values for d_{ij} may vary over several orders of magnitude, and that it is not necessarily the crystals with the highest values that are most commonly used. The technical applicability is partly also determined by other qualities, such as phase-matching properties, ease of crystal growth, mechanical strength, chemical inertness, temperature stability and light-damage threshold.

A quantity often used to characterize the optical properties of nonlinear optical materials is the Miller index:

$$\delta_{ijk} = \frac{d_{ijk}(2\omega)}{\chi_{ii}^{(1)}(2\omega)\chi_{jj}^{(1)}(\omega)\chi_{kk}^{(1)}(\omega) \cdot \epsilon_0} \quad [15]$$

where $\chi^{(1)}(2\omega)$ represents the linear susceptibility for the doubled frequency 2ω , $\chi^{(1)}(\omega)$ that for the fundamental frequency ω . One finds that for most materials δ is not far from a mean value of about $2 \times 10^{-2} \text{ m}^2 \text{ C}^{-1}$, suggesting that in a given substance nonlinear and linear susceptibilities are closely related.

Noncentrosymmetric crystals show other properties in addition to frequency conversion, for instance the linear electro-optic or Pockels effect: the linear change of the refractive index induced by an applied DC electric field. Furthermore, the point groups C_n and C_{nv} allow for the existence of a permanent electric dipole moment. Indeed, crystals such as LiNbO_3 (C_{3v}) and BaTiO_3 (C_{4v}) are well known for their ferroelectric properties. Crystals transforming according to point groups containing only rotations, such as C_m , D_m , T and O , are chiral and therefore optically active. In **Table 8** we find quartz $\alpha\text{-SiO}_2$ (D_3), LiIO_3 (C_6) and Te (D_3).

Harmonic Generation in Metal Vapours

Third-harmonic generation can in principle occur in all matter, as it is not tied to the condition of non-centrosymmetry. While the effect has been investigated in liquids and solids, the use of gases, in particular alkali metal vapours, has proved particularly interesting. In spite of the relatively low density of atoms, the third-harmonic generation efficiency can become quite high, up to 10%. The limiting laser intensity in gases is orders of magnitude higher than in condensed matter. Furthermore, the sharper transitions in gases allow strong enhancement of $\chi^{(3)}$ near resonances, especially three-photon resonances, which are electric dipole-allowed with respect to the atomic ground state. In sodium vapour this corresponds to transitions $3s \rightarrow 3p$, $3s \rightarrow 4p$, etc. Enhancement may in principle also occur via intermediate one-photon resonances, of same symmetry as three-photon resonances; or by two-photon resonances at transitions of symmetry $3s \rightarrow 4s$, $3s \rightarrow 5s$, or $3s \rightarrow 3d$, etc. The resonance enhancement of $\chi^{(3)}(3\omega)$ will evidently be diminished by concurrent multiphoton (or single-photon) absorption. In tuning ω , a compromise must be sought, whereby the anomalous dispersion of $\chi^{(3)}$ is maximized in comparison to energy dissipation through absorption.

The anomalous dispersion of $\chi^{(3)}(3\omega)$ near resonances may also be used to achieve phase-matching,

$$n(\omega) = n(3\omega) \quad [16a]$$

which in a normally dispersive isotropic medium would be impossible. Considering an alkali atom A, and assuming ω to be below, and 3ω to be above a strong $s \rightarrow p$ transition, we find

$$n_A(\omega) > n_A(3\omega) \quad [16b]$$

Phase-matching may be achieved by admixture of a buffer-gas B. Such an inert gas must be transparent at frequency 3ω and above; then

$$n_B(\omega) < n_B(3\omega) \quad [16c]$$

The relative concentration of the inert gas is adjusted, so as to have for the mixture M,

$$n_M(\omega) = n_M(3\omega) \quad [16d]$$

High conversion efficiencies have, for instance, been achieved with the mixtures Rb:Xe (10%) and Na:Mg (3.8%).

Four-Wave Mixing

Besides third-harmonic generation, there exists a large variety of four-wave mixing effects. Depending on the combination of frequencies, on the occurrence of intermediate resonances and on the polarization of the light beams involved, the manifestation of these phenomena

may be very different. We limit our considerations to a few selected examples.

Coherent Raman Spectroscopy

In coherent anti-Stokes Raman spectroscopy (CARS) two beams of frequency ω_1 and ω_2 are mixed in the sample to generate a new frequency $\omega_s = 2\omega_1 - \omega_2$. If there is a Raman resonance at $\omega_1 - \omega_2 = \Omega$, an amplified signal is detected at the anti-Stokes frequency $\omega_1 + \Omega$ (see **Figure 5**). The corresponding susceptibility $\chi^{(3)}(-\omega_4; \omega_1, \omega_2, \omega_3)$ may be written $\chi^{(3)}(-\omega_1 - \Omega; \omega_1, -\Omega_1 + \omega, \omega_1)$. The major experimental advantage of CARS and of other coherent Raman techniques is the large, highly directional signal produced, of the order of 10^4 times more intense than would be obtained for conventional spontaneous Raman scattering. Usually, CARS experiments are performed with pulsed lasers delivering a peak

${}^{(n)}[\text{SI}] = \frac{10^{-7}}{(3 \times 10^4)^{n+1}} {}^{(n)}[\text{esu}]^*$	$\text{J} \left(\frac{\text{m}}{\text{V}}\right)^{n+1}$
* The case $n=0$ corresponds to the conversion factor for a permanent electric dipole moment:	
$[\text{SI}] = \frac{1}{3} \times 10^{-11} [\text{esu}]$	$\text{J} \frac{\text{m}}{\text{V}} = \text{cm}$

power of the order of 10–100 kW. High frequency-resolution measurements with CW lasers are also possible. CARS experiments have been performed in gases, liquids and solids and on a variety of substances, ranging from diamond to aqueous solutions of biological macromolecules. Of particular interest is the use of CARS for combustion diagnostics. The coherent Raman signals can easily be separated from the luminescent background in flames.

Other related coherent Raman effects are also represented in **Figure 5**, such as the case (C) where the signal beam is detected at the Stokes frequency. The Raman-induced Kerr effect (B) may be interpreted as the quadratic influence of an electric field of frequency ω_2 on the elastic scattering of radiation at a frequency ω_1 , or vice versa. In this case the phase-matching (or wave-vector-matching) condition is fulfilled for any angle between beams 1 and 2, while in cases (A) and (C) it may only be met for certain angles of the beams with respect to each other.

Degenerate Four-Wave Mixing

The process governed by the third-order susceptibility $\chi^{(3)}(-\omega; \omega, -\omega, \omega)$ is called degenerate four-wave mixing. It may lead to a variety of highly interesting effects, one of them being that the index of refraction $n(\omega)$ becomes dependent on the incident light intensity $I(\omega)$:

$$n(\omega) = n_0(\omega) + n_2(\omega)I(\omega) \quad [17]$$

For a single-mode laser beam with a Gaussian transverse intensity distribution, the index of refraction at the centre of the beam will then be larger than at its periphery, provided $n_2(\omega)$ is positive. Thereby the medium will act as a positive lens, tending to bring the incident beam to a focus at the centre on the beam. However, only if the intensity of the laser beam is sufficiently large will this self-focusing effect be able to counteract the beam spread due to ordinary diffraction.

An effect that may also occur with other nonlinear optical phenomena, but that has been extensively studied in the frame of degenerate four-wave mixing, is phase conjugation. Here we consider not a single beam of frequency ω , but four different beams: the collinear counterpropagating pump beams 1 and 2 interfere in the $\chi^{(3)}$ -active medium to form an induced static grating. From this grating a signal wave 3, incident at a given angle with respect to 1 and 2, is scattered and reflected. The coherent reflected wave 4 is phase conjugate with respect to 3. For instance, if 3 is a forward-travelling plane wave

$$E_3(z, t) = A_3 \cos(\omega t - kz - \phi_0) \quad [18a]$$

the corresponding phase-conjugate wave 4 will be

$$\begin{aligned} E_4(z, t) &= A_4 \cos(-\omega t - kz - \phi_0) \\ &= A_4 \cos(+\omega t + kz + \phi_0) \end{aligned} \quad [18b]$$

It will travel backwards and behave as if the time t had been replaced by $-t$. A nonlinear medium susceptible to degenerate four-wave mixing can thus be used as a phase-conjugate mirror. A left circularly polarized incident beam will be reflected as a left circularly polarized beam, and not as a right circularly polarized one as would be the case upon ordinary reflection. The phase conjugation process can be thought of as the generation of a time-reversed wavefront. If the input signal wave in passing through a medium before entering the phase-conjugate mirror suffers a wavefront distortion, the phase conjugate wave reflected back through the medium will remove this distortion. The phenomenon of phase conjugation can, for instance, be used to correct for aberrations induced by amplifying media.

Particular Aspects of Nonlinear Optics

Higher Order Electromagnetic Effects

The interaction energy of a molecular system with the radiation field may formally be expanded into a multipole series. The first term in this expansion contains the electric dipole–electric field interaction; in the second term appear the magnetic dipole–magnetic field interaction and the electric quadrupole interaction with the electric field gradient of the radiation, and so on. If the wavelength of light is large compared to the molecular dimensions, the higher multipole effects tend to be small and are often negligible from an experimental standpoint. The discussion until now has therefore considered only dominant electric dipole contributions to the molecular polarizability or bulk susceptibility. However, depending on molecular symmetry, there are situations where magnetic dipole and electric quadrupole interactions may become measurable. For instance, owing to these, weak second-harmonic generation may also be observed

in some centrosymmetric crystals. Furthermore, the interplay of electric dipole, magnetic dipole and electric quadrupole interactions in chiral media leads to natural optical activity and to related higher-order nonlinear circular differential effects.

Particular nonlinear optical phenomena arise also when static electric or magnetic fields are applied. The molecular states and selection rules are thereby modified, leading, for instance, to higher-order, nonlinear-optical variants of the linear (Pockels) and quadratic (Kerr) electro-optical effect, or of the linear (Faraday) and quadratic (Cotton–Mouton) magneto-optical effect.

Incoherent Higher-Harmonic Scattering

We have seen that coherent second-harmonic generation is forbidden in liquids, even in chiral ones. This is due to the fact that the relevant molecular quantity $\alpha^{(2)}(-2\omega; \omega, \omega)$ vanishes when averaged over all possible molecular orientations:

$$\langle \alpha^{(2)}(-2\omega; \omega, \omega) \rangle = 0 \quad [19a]$$

However, the inhomogeneity of the liquid at the molecular level and the fact that every molecule is an individual scatterer of radiation are not fully taken into account. The superposition of this molecular scattered radiation is partly incoherent. It consists mainly of ‘ordinary’ Rayleigh scattering at the basic frequency ω ; but if the molecules are noncentrosymmetric, some incoherent radiation of frequency 2ω is also generated. This hyper-Rayleigh scattering, though weak, is clearly detectable with pulsed lasers of megawatt peak power. Its intensity is proportional to the square of $\alpha^{(2)}(-2\omega; \omega, \omega)$, which upon averaging over all spatial orientations in the liquid does not vanish:

$$\langle |\alpha^{(2)}(-2\omega; \omega, \omega)|^2 \rangle \neq 0 \quad [19b]$$

From the directional dependence and the depolarization ratios of the scattered radiation, information may be

gained on particular tensor elements of $\alpha^{(2)}(-2\omega)$. The method has the advantage over EFISH measurements that it is also applicable to noncentrosymmetric molecules that do not possess a permanent dipole moment, in particular to, ‘octopolar’ molecules of symmetry D_{3h} (such as tricyanomethanide $[C(CN)_3]^-$) or of symmetry T_d (such as CCl_4). It is to be expected that progress in laser technology and light detection systems will further improve the applicability of the method.

Linear, spontaneous Raman spectroscopy is a powerful tool for structural analysis of materials in the gaseous, liquid or solid state. Its scattering cross section can be increased considerably by resonance excitation, i.e. irradiation in spectral regions where there is strong absorption or by applying surface-enhanced methods like SERS (surface-enhanced Raman scattering). Also, the scattering volume, determined by the dimensions of a focused laser beam, can be as small as a few μm^2 if a microscope is incorporated in a Raman spectrometer. There are, however, cases where ordinary Raman spectroscopy has limitations in allowing the derivation of the desired information. For example, particular vibrational modes of specific symmetry are neither allowed in linear Raman scattering nor in infrared absorption, but their vibrational bands show up in what is called a hyper-Raman spectrum, because there is a nonvanishing contribution from the nonlinear part of the induced dipole moment. Also, fluorescence simultaneously excited with visible laser light may obscure the Raman scattered light. This can often be overcome by near-infrared laser excitation. Another way is to apply nonlinear coherent Raman techniques like CARS (coherent anti-Stokes Raman spectroscopy). In general, nonlinear optical properties of materials can only be obtained using nonlinear optical methods. One of the major advantages of nonlinear coherent Raman spectroscopy is its possible

high resolution of up to three orders of magnitude better than its linear counterpart. In addition, these methods allow spectral information to be obtained from scattering systems which produce a high light background like flames, combustion areas, etc. In recent years there has been a dramatic development in time-resolved linear and nonlinear Raman spectroscopy due to the availability of commercial pico- and femtosecond lasers which allows direct insight into the dynamics of molecules in their ground or excited electronic state. After a short description of the various nonlinear Raman techniques, typical applications will be given for these methods.

A Short Description of Nonlinear Raman Techniques

Spontaneous nonlinear as well as coherent nonlinear Raman methods are considered here. These are based on the contributions of the nonlinear part of the induced dipole moment (spontaneous effects) or the induced polarization (coherent effects) to the intensity of the frequency shifted light. In the first case, the Raman signal is generated in a spontaneous, incoherent but nonlinear optical process, whereas in the second case the Raman information is contained in a coherent laser beam whereby the nonlinear polarization acts as a coherent light source.

Hyper-Raman Effect

Generally, the induced dipole moment p in a molecular system is written as

$$p = \alpha E + \frac{1}{2}\beta EE + \frac{1}{6}\gamma EEE + \dots \quad [1]$$

where α is the polarizability, β the hyperpolarizability and γ the second hyperpolarizability. E is the incident electric field. The nonlinear terms in eqn [1] are usually small compared to the linear term which gives rise to normal, linear Raman scattering. However, when the electric field is sufficiently large, as is the case when a high-powered laser is focused on the sample, contributions from the second term in eqn [1] are sufficiently intense to be detected. This scattering is at an angular frequency $2\omega_L \pm \omega_R$, where ω_L is the angular frequency

Figure 2 Schematic diagram for stimulated Raman scattering as a quantum process.

(ω_L) is used for this type of excitation. We have seen that only particular Raman modes, i.e. those with highest gain factors, give rise to stimulated Stokes emission. Thus, for molecular spectroscopy in which we are interested in determining *all* Raman active modes, excitation with one strong laser field would not serve the purpose, although it would provide very high signals in the form of a coherent beam, but unfortunately, only at one particular vibrational frequency. However, the advantages of stimulated Raman scattering, being high signal strength and coherent radiation, can be fully exploited by a very simple modification of the type of excitation. The trick is simply to provide the molecular system with an intense external Stokes field by using a second laser beam at Stokes angular frequency ω_S instead of having initially the Stokes field produced in the molecular system by conversion of energy from the pump field. Thus, by keeping one of the two lasers, e.g. the laser beam at Stokes angular frequency ω_S tunable, one is now able to excite selectively coherent molecular vibrations at any desired angular frequency ω_R assuming the transitions are Raman allowed. A variety of nonlinear Raman techniques based on this idea have been developed, which combine the wide spectroscopic potentials of spontaneous Raman spectroscopy and the high efficiency of scattering, strong excitation and phasing of molecular vibrations in a macroscopic volume of substance, that are the features inherent to stimulated Raman scattering.

The following acronyms of some of these nonlinear coherent Raman techniques have been widely used: CARS, CSRS (coherent Stokes Raman spectroscopy), PARS (photoacoustic Raman spectroscopy), RIKE (Raman-induced Kerr effect), SRGS (stimulated Raman gain spectroscopy), IRS (inverse Raman scattering) also called SRLS (stimulated Raman loss spectroscopy). A schematic diagram of these methods is illustrated in **Figure 3**. The common physical aspect is the excitation of Raman active molecular vibrations and/or rotations in the field of two laser beams with angular frequencies ω_L and ω_S in such a way that their difference corresponds to the angular frequency of the molecular vibration ω_R ($=\omega_L - \omega_S$). The strong coupling between the

generated coherent molecular vibrations with the input laser fields via the third-order nonlinear susceptibility $\chi^{(3)}$ opens the possibility for various techniques.

The most powerful of these methods is CARS since a new coherent, laser-like signal is generated. Its direction is determined by the phase-matching condition

$$k_{AS} = 2k_L - k_S \quad [4]$$

where k_{AS} , k_L and k_S are the wave vectors of the anti-Stokes signal, pump and Stokes laser, respectively. The laser-like anti-Stokes signal is therefore scattered in one direction, which lies in the plane given by the two laser directions k_L and k_S and which is determined by the momentum vector diagram shown in **Figure 4**. Therefore, CARS is simply performed by measuring the signal $S(2\omega_L - \omega_S) = S(\omega_L + \omega_R)$, which is a coherent beam emitted in a certain direction. These coherent signals with anti-Stokes frequencies are generated each time the frequency difference of the input laser fields matches the molecular frequency of a Raman active transition.

The mixing of the two laser fields can also produce radiation on the Stokes side of the ω_S -laser. The direction of this coherent Stokes Raman scattering (CSRS) signal is again determined by a corresponding momentum conservation diagram, which leads to a different direction (see **Figure 3**), labelled by $S(2\omega_S - \omega_L)$. Since the CSRS signal is in principle weaker than the CARS signal, and because the former may be overlapped by fluorescence, the CARS technique is more frequently used.

The interaction of the electric fields of the two ω_L and ω_S lasers with the coherent molecular vibrations yields also a gain or a loss in the power of the lasers. The method where the gain at the Stokes frequency (labelled in **Figure 3** by $+\Delta S(\omega_S)$) is measured is generally referred to as 'stimulated Raman gain spectroscopy', whereas the 'inverse Raman scattering' (IRS) is the terminology commonly used to designate the induced loss at the pump laser frequency (**Figure 3**, $-\Delta S(\omega_L)$). IRS is also often called stimulated Raman loss spectroscopy (SRLS). In order to get full Raman information of the

Figure 3 Schematic diagram for a few techniques in nonlinear (coherent) Raman spectroscopy (CSRS: Coherent Stokes Raman Spectroscopy; SRGS: Stimulated Raman Gain Spectroscopy; IRS: Inverse Raman Spectroscopy (= SRLS: Stimulated Raman Loss Spectroscopy); CARS: Coherent anti-Stokes Raman Spectroscopy; PARS: Photoacoustic Raman Spectroscopy).

Figure 4 Momentum conservation for CARS (representation of eqn 4).

medium, it is necessary to tune the frequency difference $\omega_L - \omega_S$; then, successively all Raman-active vibrations (or rotations, or rotation-vibrations) will be excited and a complete nonlinear Raman spectrum is then obtained by measuring either newly generated signals (CARS, CSRS) or the gain (SRGS) or loss (SRLS) of the pump or the Stokes laser, respectively. In what is called broadband CARS, the Stokes (ω_S) is spectrally broad, while the pump laser (ω_L) is kept spectrally narrow, resulting in the simultaneous generation of a broad CARS spectrum. For the detection of the latter a spectrometer together with a CCD camera is needed.

In photoacoustic Raman spectroscopy (PARS), due to the interaction of the two input laser fields (ω_L, ω_S) a population of a particular energy level (ω_R) of the sample is achieved. As the vibrationally (or rotationally) excited molecules relax by means of collisions, a pressure wave is generated in the sample and this acoustic signal is detected by a sensitive microphone.

A technique which combines the high sensitivity of resonant laser ionization methods with the advantages of nonlinear coherent Raman spectroscopy is called IDSRS (ionization-detected stimulated Raman spectroscopy). The excitation process, illustrated in **Figure 5**, can be briefly described as a two-step photoexcitation process followed by ion/electron detection. In the first step two intense narrow-band lasers (ω_L, ω_S) are used to vibrationally excite the molecule via the stimulated Raman process. The excited molecules are then selectively ionized in a second step via a two- or multiphoton process. If there are intermediate resonant states involved (as state c in **Figure 5**), the method is called REMPI (resonance-enhanced multiphoton ionization)-detected stimulated Raman spectroscopy. The technique allows an increase in sensitivity of over three orders of magnitude because ions can be detected with much higher sensitivity than photons.

The nonlinear Raman techniques discussed above are special cases of a general four-wave mixing process, which is schematically illustrated in **Figure 6**. Here, three independent fields with angular frequencies ω_1, ω_2 and ω_3 may be incident upon the matter. A fourth field, which is phase coherent relative to the input fields, is then generated at angular frequency $\omega = \omega_1 - \omega_2 + \omega_3$. When the angular frequency difference $\omega_1 - \omega_2$ equals

Figure 5 Energy-level diagram illustrating the two excitation steps of ionization-detected stimulated Raman spectroscopy (IDSRS).

Figure 6 Schematic diagram representing the four-wave mixing process: a polarization is generated at the frequency $\omega = \omega_1 - \omega_2 + \omega_3$.

the Raman excitation angular frequency ω_R , the signal wave at ω is enhanced, indicating a Raman resonance. For example, a CARS signal is Raman resonantly generated when $\omega_1 = \omega_3 = \omega_L$, $\omega_2 = \omega_S$ and $\omega_L - \omega_S = \omega_R$.

Applications

Applications of Spontaneous Nonlinear Raman Spectroscopy (Hyper-Raman Scattering)

Since the discovery of the phenomenon in 1965, hyper-Raman spectra have been observed in all three states of aggregate. However, reasonable signal-to-noise ratios could only be obtained for a convenient measurement time after the development of fast pulsed, high power lasers and highly sensitive detectors (multichannel diode arrays or charge-coupled devices (CCDs)). Before that time only a few gases had been studied which included ethane, ethene and methane. Only vibrational spectra of modest resolution have been obtained in these studies. A number of group IV tetrahalides have been studied in the liquid phase. Other liquids whose Raman spectra have been reported include water and tetrachloroethene. Probably most hyper-Raman work was performed in crystals: NH_4Cl , NH_4Br , calcite, NaNO_2 , NaNO_3 , LiNbO_3 , SrTiO_3 , caesium and rubidium halides, rutile, PbI_2 , CuBr , diamond and quartz. Stimulated hyper-Raman scattering has been observed from sodium vapour, resonance hyper-Raman scattering from CdS and surface-enhanced hyper-Raman scattering from SO_3^{2-} ions adsorbed on silver powder.

Technological advances, i.e. CW pumped acousto-optically Q-switched Nd:YAG lasers with repetition rates of up to 5 kHz combined with multichannel detection systems have increased the ease of obtaining hyper-Raman signals. By making use of this advanced technology, hyper-Raman spectra of benzene and pyridine could be obtained. Spectra from benzene, deuterated benzene and carbon tetrachloride have been measured with high signal-to-noise ratios. As examples, we show in **Figure 7** the hyper-Raman spectra of benzene and deuterated benzene. The observed hyper-Raman bands are labelled by numbers (4, 6, 10, 13, 14, 20) and correspond to the ν_4 (A_{2u}), ν_6 (B_{1u}), ν_{10} (B_{2u}), ν_{13} (E_{1u}), ν_{14} (E_{1u}) and ν_{20} (E_{2u}) vibrations of C_6D_6 , respectively. **Figure 8** shows the low-lying vibrational energy levels for C_6D_6 grouped by their activity involving transitions from the ground state, i.e. Raman, IR, hyper-Raman (HR) and none of the above which are grouped as silent. Note that in the third column four modes with energy below 1500 cm^{-1} are only hyper-Raman active and three modes of symmetry A_{1u} and E_{1u} are both IR and hyper-Raman active. Except for the ν_{19} (E_{2u}) mode all hyper-Raman active modes can be found in the spectrum displayed in **Figure 7**. The modes of class B_{2g} are active in the second hyper-Raman effect which is controlled by the fourth rank second hyperpolarizability tensor γ .

Hyper-Raman scattering under resonance conditions for molecules in the gas phase was observed in 1993. High quality rotational resonance hyper-Raman spectra of NH_3 were obtained using blue incident radiation at half the $\tilde{X} \rightarrow \tilde{A}$ transition energy. Also hyper-Raman scattering of

Figure 7 Hyper-Raman spectra of C_6H_6 excited with a Nd:YAG laser ($\lambda_0 = 1.064\text{ nm}$) Q-switched at 1 kHz (A) and of C_6D_6 in the lower spectrum with the laser Q-switched at 6 kHz (B). methyl iodide for excitation with a laser line which has been tuned through the two-photon resonance with the absorption band of a predissociative Rydberg transition in the VUV (175–183 nm) was reported. Similarly to linear resonance Raman scattering, overtones or combination bands can also be observed for resonantly excited hyper-Raman scattering. An example is given in **Figure 9** where several higher order modes of methyl iodide can be observed.

The use of CW pumped acousto-optically Q-switched Nd:YAG lasers (repetition rates of 5 kHz), synchronously gated photomultiplier tubes, and synchronously gated two-dimensional single-photon counting detectors has improved the signal-to-noise ratio of hyper-Raman spectra. Considerable further improvements have been obtained with mode-locked pulses (at 82 MHz) from a Nd:YAG laser to observe the surface-enhanced hyper-Raman signal from pyridine adsorbed on silver. In these studies, hyper-Raman signals were observed with intensities close to spontaneous Raman scattering. It was shown that surface-enhanced hyper-Raman scattering (SEHRS) has become a useful spectroscopic technique. In view of the recent advances in laser and detector technology, significant improvement in SEHRS sensitivity will come rapidly from the use of an intensified CCD camera for hyper-Raman signal detection and the use of a continuously tunable mode-locked Ti:sapphire laser as the excitation source.

Applications of Coherent Anti-Stokes Raman Spectroscopy (CARS)

The advantages of CARS, i.e. high signal strength, very high spectral or temporal resolution, discrimination

against fluorescence etc., have opened new ways to study molecular structure. In the following some selected examples will be given to demonstrate the capability of this nonlinear coherent technique.

The 1980s and 1990s saw a remarkable growth in the number of CARS applications to molecular and physical properties, particularly in the field of gas-phase systems. The latter are challenging because of low sample densities and the narrow transition line widths make them attractive for high resolution studies. Gas-phase CARS spectra have been obtained at pressures down to a few pascal, at temperatures ranging from a few K to 3600 K, and at a resolution better than about 10^{-3} cm^{-1} .

Mainly, the Q-branches of simple molecules, like di-, tri-, and four-atomic as well as spherical XY_4 top molecules have been studied. As an example **Figure 10** shows the Q-branch of methane. The complicated rotational structure seen there has been resolved by applying this powerful nonlinear Raman technique. This very high

resolution of the order of 10^{-3} cm^{-1} allows us to study in detail collisional effects, which is of particular importance as a basis for the determination of temperatures and pressures.

One very active area of the gas-phase CARS technique has been the remote sensing of temperature and species in hostile environments such as gas discharges, plasmas, flames, internal combustion engines, and the exhaust from jet engines. The high signal intensity and the excellent temporal and spectral resolution of CARS make it a favourite method for such studies. For example, CARS has been used to measure state populations and changes in discharges of H_2 , N_2 and O_2 at pressures ranging from a few kPa down to 0.6 Pa. Also, gas-phase CARS can be employed to monitor SiH_2 intermediates in their investigations of silane plasmas commonly used in amorphous silicon deposition processes. Combustion studies in engines include thermometry in a diesel engine, in a production petrol engine, and thermometry and species measurements in a fully after burning jet engine. Investigations on turbulent and sooting flames were performed.

Temperature information from CARS spectra derives from spectral shapes either of the Q-branches or of the pure rotational CARS spectra of the molecular constituents. In combustion research it is most common to perform thermometry from nitrogen since it is the dominant constituent and present everywhere in large concentration despite the extent of chemical reaction. The Q-branch of nitrogen changes its shape due to the increased contribution of higher rotational levels which become more populated when the temperature increases. **Figure 11** displays a calculated temperature dependence of the N_2 CARS spectrum for experimental parameters typically used in CARS thermometry. Note that the wavenumber scale corresponds to the absolute wavenumber value for the $\sim 2320\text{ cm}^{-1}$ Q-branch of N_2 when excited with the frequency doubled Nd:YAG laser at 532 nm ($\cong 18\,796\text{ cm}^{-1}$), i.e. $\tilde{\nu}_{AS} = 18\,796 + 2320 = 21\,116\text{ cm}^{-1}$. The bands lower than about $21\,100\text{ cm}^{-1}$ are due to the rotational structure of the first vibrational hot band.

For the case that there are not too many constituents in the gas under investigation, the use of the pure rotational CARS technique may be superior to vibrational CARS thermometry since the spectra are easily resolvable (for N_2 the adjacent rotational peaks have a spacing of approximately 8 cm^{-1}) compared with the congestion of the rotational lines in the vibrational bands of the Q-branch spectra (see **Figure 11**). An experimental comparison of rotational and vibrational CARS techniques, under similar conditions, has been made that demonstrates that rotational CARS may be viable for flame-temperature measurements up to 2000 K. Of course, the pure rotational approach cannot be applied for spherical molecules which have no pure rotational CARS spectrum. An elegant method, using Fourier

analysis based on the periodicity of pure rotational CARS spectra, has been introduced.

In addition to temperature measurements the gas-phase CARS technique also provides information on the fluctuating properties occurring for instance in turbulent combustion systems. However, concentration measurements are more difficult to perform than temperature ones because the absolute intensity is required, while temperature measurements are only based on the shape of the spectrum. Simultaneous information on the relative concentrations between several species are easier to obtain.

Quantitative gas-phase CARS spectroscopy has also been applied to probing species in a laboratory chemical reactor

and to temperature measurements inside incandescent lamps. Another interesting area is that of CARS applied to free expansion jets. The key benefits of this technique are the spectral simplification of cold molecules and the increased concentrations of small van der Waals complexes obtained under the non-equilibrium jet conditions.

CARS is also used for the study of samples in the condensed phase. The major experimental advantage of CARS (and most nonlinear coherent Raman techniques) is the large signal produced. In a typical CARS experiment in a liquid or a solid, the applied laser power of the pump and Stokes laser ($10^4 - 10^5$ W) generates an output power of up to 1 W, while conventional Raman scattering would give a

Figure 13 Resonance CARS spectra of a substituted diacetylene single crystal (FBS-DA) at 10 K. The pump wavelength λ_p used is labelled for each spectrum. (a) and (b) show CARS spectra of the P-colour zone, and (c)–(l) those for the Y-colour zone. Spectra on the left side correspond to the C=C stretching region, and those on the right side to the C≡C stretching region. For further details, see text. collected signal power of $\sim 10^{-4}$ W with the same lasers. Since the CARS output is directional, the collection angle can be five orders of magnitude smaller than that needed in spontaneous scattering. Taken together, these two factors imply that CARS is nine orders of magnitude less sensitive to sample fluorescence than spontaneous scattering. The

advantage is actually even greater since the CARS signal is at higher frequency than any of the input laser frequencies.

While it is nearly impossible to obtain Raman spectra of highly luminescent materials, e.g. dye solution, it was the CARS technique which first overcame this problem because of the reasons mentioned above. As an example

Figure 14 High resolution multi-pass stimulated Raman gain spectrum (SRGS) of the Q-branch of the lower component of the Fermi resonance diad of $^{12}\text{C}^{16}\text{O}_2$ at a pressure of 200 Pa (1.5 Torr). Reproduced by permission of John Wiley & Sons from Saint-Loup R, Lavorel B, Millot G, Wenger C, and Berger H (1990) Enhancement of sensitivity in high-resolution stimulated Raman spectroscopy of gases. *Journal of Raman Spectroscopy* 21: 77–83.

the CARS spectrum of a rhodamine 6G (R6G) water solution is displayed in **Figure 12**. The vibrational modes of the strongly luminescent R6G molecule can be seen. It should be mentioned at this point that by long wavelength excitation, i.e. for example excitation with the $1.064\ \mu\text{m}$ line of a CW Nd:YAG laser or by making use of the SERS effect luminescence-free linear Raman spectra can be obtained. Since the latter methods are in any case much easier to perform than CARS or other nonlinear Raman techniques, they are to be preferred. However, if one is interested in obtaining structural as well as electronic properties of absorbing materials through resonance excitation, there are many cases where linear resonance Raman spectroscopy is limited because of the mentioned strong luminescence.

On the other hand, many, particularly organic, substances show considerable third-order nonlinear susceptibilities $\chi^{(3)}$, as for example polyacetylenes, polydiacetylenes or chlorophyll. For such systems, resonance CARS spectroscopy is a suitable tool to obtain resonance Raman information via the anti-Stokes, coherent spectroscopic method. However, in performing resonance CARS spectroscopy in solids one must realize that this technique results in a fairly complicated arrangement between the sample and the coherent beams. First, the phase-matching conditions (eqn [4], **Figure 4**) have to be obeyed, where the momentum vectors depend also on the refractive index of the solid media. Therefore a continuous adjustment of the

crossing angle between the incident laser beams (k_L , k_S) as well as of the angle between the pump laser beam and the CARS beam (k_L , k_{AS}) is required during the scan of the CARS spectrum. Secondly, in order to excite particular phonons in the crystals, the difference between the pump and the Stokes beam wave vectors must coincide with the wave vector of the coherently excited phonon in the crystal ($k_L - k_S = k_{\text{phonon}}$). Depending on the strength of absorption and sample thickness, CARS in solids is performed either in transmission or in reflection (back-scattering CARS).

As an example of resonance CARS studies in solids, for which a linear resonance Raman study has been impossible to perform because of simultaneous strong luminescence, we considered here investigations on colour zones in substituted diacetylene crystals originating from partial polymerization.

For a long time it has been known that diacetylene monomer single crystals undergo, upon thermal annealing or exposure to high-energy radiation, topochemical solid-state polymerization. From this reaction, polymer chains are formed which have a substantial π -electron delocalization, forming a pseudo-one-dimensional electronic system. Colour zones occur in such crystals due to different chain lengths and CARS studies were performed on these zones in crystals with low polymer content, where the polymer chains were embedded in the monomer matrix. As mentioned, resonance

Raman excitation within the strong absorption of the polymer chains, i.e. within the absorption of the colour zone, produced high luminescence levels which obscured the bands in linear Raman spectroscopy. In contrast, luminescence-free resonance CARS spectra can be obtained, as shown in **Figure 13** for the case of an FBS DA crystal at 10 K (FBS = 2,4-hexadiynylene-di-p-fluorobenzene sulfonate, DA = diacetylene). On the left and right panels of **Figure 13** CARS spectra are displayed for

the region of the C=C and C $\equiv$ C stretching region around 1500 cm^{-1} and 2100 cm^{-1} , respectively. Spectra (a) and (b) are those of the P colour zone (P = principal) and (c)–(l) those of the Y-colour zone (Y = yellow). Note the very different CARS intensities as well as band shapes for the various excitation wavelengths of the pump laser (λ_p , which corresponds to ω_L of the CARS process as outlined above) which are due to different resonant enhancements. Comparing spectrum (k) with (c), for

example, shows in addition the very high dynamic range (at least four orders of magnitude) inherent in this type of spectroscopy. Analysing the CARS spectra together with the absorption spectra of several substituted DA crystals, one is able to derive important structural as well as electronic properties of this type of crystal.

It should be mentioned that there are some disadvantages of CARS: (i) an unavoidable electronic background nonlinearity that alters the line shape and can limit the detection sensitivity; (ii) a signal that scales as the square of the spontaneous scattering signal (and as the cube of the laser power), making the signals from weakly scattering samples difficult to detect; and (iii) the need to fulfil the phase matching requirements. While other techniques avoid these difficulties, CARS still remains the most popular coherent nonlinear technique.

Applications of Stimulated Raman Gain and Inverse Raman Spectroscopy (SRGS, IRS)

The advantages of SRGS and IRS are that (in contrast to CARS) the signal is linearly proportional to the spontaneous Raman scattering cross section (and to the product of the two laser intensities), and that the phase-matching condition is automatically fulfilled. The fact that the resolution of the nonlinear Raman techniques is limited only by the laser line widths gives the stimulated Raman techniques particular appeal under conditions where interference from background luminescence is problematic or in situations where very high resolution is required. The main disadvantage of these techniques, however, is that they are quite sensitive to

laser noise. The latter requires high stability in laser power.

Due to complexity, only a few stimulated Raman gain and loss spectrometers with a main application in high resolution molecular spectroscopy have been built since the fundamental developments around 1978.

Here, we present an instructive example for each of the two techniques (SRGS, IRS) emphasizing the high resolution capability of these methods.

The Q-branches of numerous molecules, particularly of linear and spherical top molecules have been analysed by means of SRGS and IRS. As an example of a high resolution SRGS spectrum we show in **Figure 14** the spectrum of the Q-branch of the lower component of the Fermi resonance diad of $^{12}\text{C}^{16}\text{O}_2$ at 1285 cm^{-1} . The spectrum has been recorded at a pressure of 200 Pa (1.5 Torr). The excellent agreement with a calculation assuming Voigt line profiles is demonstrated by the residual spectrum in the upper trace.

An example for high-resolution IRS is given in **Figure 15**, where the ν_2 Q-branch of CH_3D is displayed. This spectrum represents a Doppler-limited spectrum of the C–D stretching band. The authors were able to assign the observed transitions by performing a theoretical fit to the observed data which allowed them to refine some of the rotational–vibrational constants.

Applications of Photoacoustic Raman Spectroscopy (PARS)

As discussed above in photoacoustic Raman spectroscopy (PARS) the energy deposited in the sample by excitation

Figure 17 Ionization-detected stimulated (IDSRS) spectra of benzene in the region of overlap between O-branch transitions of ν_{16} and the S-branch transitions of $\nu_2 + \nu_{18}$. (a) UV laser tuned to $36\,467\text{ cm}^{-1}$; (b) UV laser tuned to $36\,496\text{ cm}^{-1}$. of, for example, a vibration by the stimulated Raman process leads to pressure increases through relaxation to translational energy and can therefore be detected by a sensitive microphone.

When the pump (ω_L) and Stokes (ω_S) beams have only small frequency differences, as can be achieved, for example, by using a frequency-doubled Nd:YAG laser for ω_L and a dye laser with amplifier pumped by the third harmonic of the same Nd:YAG laser for ω_S , the recording of pure rotational PARS spectra becomes possible. Such a spectrum at medium resolution is shown in **Figure 16**. The striking feature of this spectrum is the absence of a

strong Rayleigh component at the pump wavelength (532 nm) because at that wavelength no energy is deposited in the sample.

The PARS technique has been extended to study vibrational-rotational transitions with high resolution ($\sim 0.005\text{ cm}^{-1}$). For example, a high resolution PARS spectrum of the lower component of the Fermi resonance diad of CO_2 at a pressure of 1.6 kPa (= 11 Torr) could be obtained with high signal-to-noise ratio.

In another PARS study it was shown that photoacoustic Raman spectroscopy is a sensitive technique for obtaining Raman spectra of hydrogen-bonded complexes

in the gas phase. PARS spectra of the CN stretching ν_1 region of HCN as a function of pressure revealed bands which could be assigned to HCN dimers and trimers.

Applications of Ionization-Detected Stimulated Raman Spectroscopy (IDSRS)

Above we have discussed how the sensitivity in determining Raman transitions can be enormously increased by employing nonlinear Raman schemes in which the shifts in vibrational state populations due to stimulated Raman transitions are probed by resonance-enhanced multiphoton ionization. As ions can be detected with much higher sensitivity than photons, the signal-to-noise ratio in the nonlinear Raman spectrum of, for example, NO could be improved by a factor of 10^3 by this method. In fact, one can obtain sufficient sensitivity to characterize the Raman transitions of species even in molecular beams. The high sensitivity of IDSRS made it, for instance, possible to investigate the degenerate Fermi doublet of benzene in such a molecular beam experiment. The two Fermi subbands could be recorded separately by selectively tuning the UV laser into resonance with electronic transitions from one of the two states. When the Stokes laser is tuned, then the rovibrational structure of only one Raman transition is recorded. **Figure 17** shows in the upper part the lines belonging to ν_{16} and in the lower part those assigned to $\nu_2 + \nu_{18}$ in the same spectral region.

P	polarization of charge
t	time
x	space
θ	angle between beams
μ	transition dipole moment
ω	angular frequency
$\chi^{(n)}$	complex susceptibility tensor element

Introduction

When exposed to large electric fields generated by intense sources of light (e.g. a laser), the charges in a material exhibit a nonlinear response. The resulting induced polarization of charge P is described by the series expansion

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \dots \quad [1]$$

where the second-, third-, and higher-order terms account for the nonlinear contribution. The coefficients $\chi^{(n)}$ are separate complex susceptibility tensor elements that describe the magnitude of the nonlinear contribution. The E s are the applied electric fields from the lasers with the form $E = A \exp[-i(\mathbf{k}x - \omega t)]$, where $\mathbf{k}$ is the propagation or wave vector, ω is the angular frequency, and x and t indicate space and time, respectively. Since $\chi^{(1)} \gg \chi^{(2)} \gg \chi^{(3)}$, lasers with sufficiently large E s are required in order for the second and third terms to be significant. Most nonlinear Raman techniques rely on the third-order term to drive the induced polarization that generates an intense output beam.

Nonlinear spectra are produced by monitoring the intensity of the output beam while varying some parameters, such as the frequency ω of one or more of the laser beams. When the difference in frequency between two laser beams matches the frequency of a

Raman-active mode, the resulting resonance enhances the nonlinear optical effect, causing a change in the intensity of the output beam. The result is a peak in the nonlinear Raman spectrum. Some nonlinear Raman techniques that use this approach are given in Table 1.

Coherent Anti-Stokes Raman Spectroscopy (CARS)

Perhaps the best-known and most widely used form of nonlinear Raman spectroscopy is CARS. One of its attractive properties is that it generates an intense beam of light at a new frequency that is anti-Stokes (blue shifted) and spectrally separable from the input beams. Therefore, CARS is not susceptible to fluorescence (red shifted) and mechanisms (e.g. non-local effects) that can affect elastic scattering of the input beams.

CARS relies on the third-order term from eqn [1] which can be expanded as

$$\chi^{(3)}A_1A_2A_3 \exp[-i((\pm \mathbf{k}_1 \pm \mathbf{k}_2 \pm \mathbf{k}_3)x - (\pm \omega_1 \pm \omega_2 \pm \omega_3)t)] \quad [2]$$

where the subscripts are labels for three input laser fields. This term can cause new light to be generated at frequency combinations corresponding to $\pm \omega_1 \pm \omega_2 \pm \omega_3$. CARS involves the generation of light at the specific output frequency $\omega_4 = \omega_1 - \omega_2 + \omega_3$. Raman-like peaks in the spectra are obtained when $\omega_1 - \omega_2$ is tuned to the frequency of Raman-active vibrations or rotations. Judicious selection of the three input fields so that ω_1 or ω_4 matches the frequencies of coupled higher lying electronic levels can lead to the same type of enhancement observed in resonance Raman spectroscopy.

The intensity of the generated CARS beam can be written as

$$I_4 = \frac{144\pi^4\omega_4|\chi^{(3)}|^2I_1I_2I_3L^2}{c^4n_1n_2n_3n_4} \left\{ \frac{\sin(L\Delta k/2)}{L\Delta k/2} \right\}^2 \quad [3]$$

where the I s correspond to the intensities of the beams, n is the refractive index, and c is the speed of light. This equation indicates that the output beam intensity varies as the product of the input laser intensities and the square of their overlap length L in the sample. The squared sinc function on the right is equal to 1 when the

Table 1 Comparison of some nonlinear Raman techniques

Technique	Comment	Variable	Output	Advantages	Disadvantages
CARS	Most popular form of non-linear Raman	ω_1 or ω_2	Intensity of newly generated light at $\omega_4 = \omega_1 - \omega_2 + \omega_3$	Fluorescence-free, intense signal at new wavelength	Phase matching required owing to dispersion, nonresonant background, complex line shape
CSRS	Nonparametric version of CARS	ω_1 or ω_2	Intensity of newly generated light at $\omega_4 = \omega_1 - \omega_2 + \omega_3$	Intense signal at new wavelength, can be used to observe dephasing effects	Susceptible to fluorescence, phase matching required due to dispersion, nonresonant background, complex line shape
SRG	Induced amplification of ω_2	Modulation of ω_1	Increase in intensity of ω_2 when $\omega_1 - \omega_2 = \omega_{\text{Raman}}$	No phase matching, no nonresonant background, linear with concentration	Sensitivity limited by stability of probe laser, difficult to multiplex
SRL	Induced reduction in intensity of ω_1	Modulation of ω_2	Decrease in intensity of ω_1 when $\omega_1 - \omega_2 = \omega_{\text{Raman}}$	No phase matching, no nonresonant background, linear with concentration	Sensitivity limited by stability of probe laser, difficult to multiplex
RIKES	Raman-induced birefringence	Modulation of ω_2 , ω_1 is CW	Induced change in ω_1 polarization for $\omega_1 - \omega_2 = \omega_{\text{Raman}}$	Nonresonant background can be suppressed, no phase matching	Limited sensitivity, susceptible to turbulence and birefringence from windows, optics, sample
DFWM	Laser-induced grating		Beam of light at $\omega_4 = \omega_1 = \omega_2 = \omega_3$	Very sensitive, no phase matching	Multiple mechanisms (local and nonlocal), not a Raman technique
IRSFG	$\chi^{(2)}$ process, IR and Raman active		Intensity of newly generated light at $\omega_3 = \omega_1 + \omega_2$	Surface-specific	Requires tunable coherent IR source, relatively low signal intensity

phase of the input and output beams is matched (i.e. phase matched).

Peaks in the nonlinear Raman spectrum are produced when $\chi^{(3)}$ changes while varying the frequencies of the input beams. The intensity of the CARS process varies as the squared modulus of the nonlinear susceptibility as shown in eqn [3]:

$$\chi^{(3)} \propto N \sum \frac{\mu_{ac}\mu_{cb}\mu_{bd}\mu_{da}}{(\omega_c - \omega_1 - i\Gamma_{ac})(\omega_b - (\omega_1 - \omega_2) - i\Gamma_{ab})(\omega_d - (\omega_1 - \omega_2 + \omega_3) - i\Gamma_{ad})} \quad [4]$$

which is a fourth-ranked tensor that is summed over all possible states. N is the concentration, and the μ s are transition dipole moments. The three products in the denominator are resonant terms that approach a minimum value of $i\Gamma$ (the dephasing linewidth) when a laser combination frequency matches the frequency of a level. The labels for the transition moments and the angular frequencies correspond to those shown in the CARS energy level diagram in **Figure 1**.

Equation [4] can be used to compare spectra from incoherent Raman and CARS. First, while conventional Raman varies linearly with the sample concentration, the CARS signal varies as $|\chi^{(3)}|^2$ and is therefore proportional to the square of the N . Furthermore, $\chi^{(3)}$ is a summation of terms, including both resonant and

nonresonant contributions ($\chi^{(3)} = \chi_{\text{res}}^{(3)} + \chi_{\text{nr}}^{(3)}$). Contributing terms near resonance are primarily imaginary ($i\Gamma$ dominates), while nonresonant terms are primarily real ($i\Gamma$ is negligible). The nonresonant contributions result in a non-zero background, which determines the detection limits of the technique to around 0.1% in the condensed phase and 10 ppm in the gas phase. Therefore,

Figure 1 Energy level diagram for CARS, Raman, CSRS, DFWM, RIKES/SRG, and IRSFG. The dotted horizontal lines represent virtual levels and the solid horizontal lines represent ground, rotational, or vibrational levels. The output frequency corresponds to the downward arrow furthest to the right in each diagram. Electronic enhancement may be achieved if the virtual levels are replaced by real levels.

although the nonlinear signal is more intense, the sensitivity of CARS for trace analysis is not necessarily higher than that of more conventional techniques. Finally, since the observed signal goes as $|\chi^{(3)}|^2$, the cross-product between the $\chi_{\text{res}}^{(3)}$ and $\chi_{\text{nr}}^{(3)}$ can contribute dispersion-like character. Therefore, CARS peaks often have asymmetric line shapes, especially when the nonresonant background is large relative to the resonant peak.

Other Nonlinear Raman Techniques

In addition to CARS, other closely related but less commonly used nonlinear Raman techniques have been developed. The energy level diagram for coherent Stokes Raman spectroscopy (CSRS) is shown in **Figure 1**. Unlike CARS, CSRS is nonparametric; the final state is not the same as the initial state. Therefore, CSRS spectra may exhibit extra peaks due to coherence dephasing. Furthermore, the CSRS output beam is generated to the Stokes (lower frequency) side of ω_3 . CSRS is therefore more susceptible to spectral interference from fluorescence and Rayleigh scattering of the input beams.

Other Raman-based forms of nonlinear spectroscopy include stimulated Raman gain (SRG) or stimulated Raman scattering, stimulated Raman loss (SRL) or inverse Raman spectroscopy, and Raman-induced Kerr effect spectroscopy (RIKES). Some information on these techniques are provided in **Table 1**. Many of these other forms do not produce light at wavelengths that are different from the input lasers, do not involve phase matching, and may be susceptible to multiple effects that may interfere with the measurement. Consequently, these techniques have not been as widely used as CARS.

Other Nonlinear Techniques

Several other forms of nonlinear spectroscopy have been developed that are not strictly based on Raman-active vibrations or rotations. Degenerate four-wave mixing (DFWM) is a $\chi^{(3)}$ technique where all input and output frequencies are identical. Because it does not involve the generation of light at new frequencies, it can rely on non-local mechanisms other than the local electronic polarizability (e.g. electrostriction). The selection rules for DFWM are closely related to those of one-photon techniques (e.g. absorption). DFWM using infrared beams is therefore used to probe infrared absorbing transitions instead of Raman-active transitions.

Finally, other nonlinear techniques can be used to obtain spectra that are both infrared and Raman active. Infrared sum frequency generation (IRSFG) is a surface-specific nonlinear technique that relies on $\chi^{(2)}$. The coherently generated output beam has a frequency of $\omega_3 = \omega_1 + \omega_2$, where ω_1 is in the infrared region. The selection rules for IRSFG require that the medium be

anisotropic and that the transition be both IR and Raman active.

Although the remainder of this article will focus primarily on CARS, the described advances in instrumentation and methods typically also benefit other forms of nonlinear spectroscopy.

Experimental Setup

Conventional Raman spectroscopy involves the collection and spectral analysis of light that is incoherently scattered in many directions. Nonlinear Raman spectroscopy requires careful alignment and overlap of multiple laser beams in order to produce a coherent output beam. Phase matching is also required for CARS and some other closely related nonlinear techniques (e.g. CSRS).

Overlap

Nonlinear Raman spectroscopy requires spatial and temporal overlap of the input beams. All beams should be spatially overlapped, which can be achieved by ensuring that all beams are parallel or collinear as they enter the lens that focuses them into the sample. Spatial overlap at the sample position can then be verified by temporarily placing a knife edge or a small pinhole into the focal point overlap region. If the spatial properties of the beams (e.g. divergence and diameter) are poor or not well matched, spatial filters and additional lenses may be used to improve the quality of the overlap. Temporal overlap of the incoming beams at the sample is also essential, since the response times of some mechanisms (i.e. the local electronic polarizability) are on the order of femtoseconds. Therefore, most CARS systems use a single fixed-wavelength laser to pump all tunable lasers. Temporal overlap is then optimized using optical paths that delay any beams that would otherwise arrive at the sample prematurely. Temporal overlap may be confirmed by scattering light at the overlap region into a fast photodiode when working with nanosecond pulses. For shorter pulses, temporal overlap may involve the use of an autocorrelator. Finally, the frequency and polarization of input beams and the detection system should be adjusted as needed. Polarization optics may be inserted both in the pump beams and in the detection system.

Phase Matching

Phase matching is required for CARS experiments in normally dispersive media (i.e. condensed phase samples). The exponential terms from eqn [2] can be written as $\omega_1 + \omega_3 = \omega_2 + \omega_4$ (conservation of energy) and $k_1 + k_3 = k_2 + k_4$ (conservation of momentum). The magnitude of each k vector is $|k| = n\omega/c$, and the

direction corresponds to the direction of the beam as it propagates through the sample. In a dispersionless material (the refractive index is constant for all wavelengths of light) both conditions may be satisfied using collinear alignment of all beams (see **Figure 2a**). For most materials, however, the refractive index increases with the frequency of light. Since k_4 has the highest frequency and therefore the largest refractive index, it is disproportionately long, causing $|k_2| + |k_4|$ to be greater than $|k_1| + |k_3|$ (see **Figure 2b**). The discrepancy in length indicates the presence of a phase mismatch Δk between the beams. The result is a loss in the efficiency of the output beam, described by the squared sinc function in eqn [3] and shown in **Figure 3**.

Figure 2d shows how this problem can be fixed by introducing an angle between k_2 and k_4 to match the

Figure 2 The refractive index in a sample with normal dispersion increases with decreasing wavelength. The phase-matching diagrams are as follows: (a) collinear phase matching in the gas phase where dispersion is negligible (e.g. gas phase); (b) phase mismatch Δk encountered when using collinear geometry in a sample with normal dispersion; (c) possible arrangement in RIKES, SRG, and SRL where the angle α between beams is not critical and phase-matching calculations are not needed; (d) conventional phase matching in condensed phase ($\Delta k=0$); (e) BOXCARS phase matching; and (f) folded BOXCARS phase matching.

Figure 3 Effect of the phase matching Δk on the intensity (I) of the CARS output beam.

phases of the beams. The fact that k_4 is emitted along its own unique trajectory provides the ability to separate spatially the CARS output beam from the pump beams, other nonlinear processes, or other sources of spectral interference. Additional spatial discrimination may be achieved using BOXCARS phase matching, where an angle is introduced between k_1 and k_3 to increase further the angle between k_4 and k_2 (see **Figure 2e**).

In the gas phase, dispersion may be negligible, making collinear phase matching possible (see **Figure 2a**). However, the BOXCARS approach is often preferred because it allows spatial discrimination between the input and output beams. Additional spatial discrimination may be achieved using a three-dimensional form called folded BOXCARS (see **Figure 2f**).

Unfortunately, the angles required for phase matching often vary when the laser frequencies change. The magnitude of each k vector depends upon both its frequency ω and the frequency-dependent refractive index n . Changing the frequency of any one of the four beams forces one other beam frequency to change. Therefore, the scanning of beam frequencies while producing spectra usually requires adjustment of the phase matching angles in order to avoid a phase mismatch. Without correction, the growing phase mismatch can be approximated by

$$\Delta k \approx \frac{n\Delta\omega}{c} \sqrt{2 - 2\cos\theta} \quad [5]$$

where n is the approximate refractive index, $\Delta\omega$ is the change in frequency, and θ is the angle between the two beams with changing frequencies. Therefore, this phase mismatch problem can also be minimized by reducing the angle θ between changing k vectors.

Instrumentation

In conventional Raman spectroscopy, the required instrumentation includes (1) a fixed-wavelength narrow-band laser, (2) a filter, monochromator, or some other means for rejecting Rayleigh scattering, and (3) a detection system for spectrally analysing and measuring the intensity of the scattered light. Factors such as spectral resolution and scan range depend primarily upon the detection system. For CARS and other forms of nonlinear Raman spectroscopy, however, the scanning of wavelengths is often performed by the laser instead of the detection system. Therefore, the quality of the spectra depends primarily upon the lasers.

Lasers

Most nonlinear Raman spectrometers include a fixed-wavelength laser that pumps one or more continuously tunable lasers. Some common pump lasers include the

Figure 4 Experimental setups, illustrating two possible CARS spectrometers using (a) a single dye laser where $\omega_1 = \omega_3$, and (b) an optical parametric oscillator for single-wavelength detection.

Nd:YAG laser, excimer laser, nitrogen laser, and argon ion laser. The traditional source for broad tunability has been the dye laser, which is tunable over several tens of nanometres. For example, a common configuration involves the second harmonic of an Nd:YAG laser ($\lambda = 532$ nm) split into two beams, one for pumping a dye laser (ω_2) and the other for both ω_1 and ω_3 (see **Figure 4a**). Tuning of the dye laser frequency causes the frequency difference $\omega_1 - \omega_2$ to pass through Raman-active rotations or vibrations.

However, dye lasers have been replaced or enhanced by sources that are more broadly tunable or that allow extension of wavelength into regions that are inaccessible by dyes. Difference frequency generation, sum frequency generation, and stimulated Raman scattering are nonlinear optical processes that can generate tunable light in the infrared and UV regions. Ti:sapphire lasers, tunable over a range of roughly 700–900 nm, are widely commercially available in both CW and pulsed (mode-locked) versions. Optical parametric devices such as the optical parametric oscillator (OPO) and the optical parametric amplifier (OPA) are nonlinear devices that are continuously tunable over wide regions of the spectrum. For example, optical parametric oscillators (OPOs) pumped by the third harmonic ($\lambda = 355$ nm) of an Nd:YAG laser can produce tunable signal and idler beams that cover a range of roughly 450–1800 nm.

The temporal behaviour of the laser source is also an important factor to consider. CW dye lasers can have low noise and extremely narrow bandwidths (10^{-4} cm $^{-1}$) for high-resolution work. However, their peak powers are low ($\sim$ watts), making their use with CARS possible for only the strongest Raman transitions. Unless extremely high resolution work is needed, Q-switched lasers are preferable because they can generate high peak power (MW to GW) nanosecond pulses with sufficiently narrow

bandwidth (0.01 – 0.2 cm $^{-1}$) for most Raman applications. The noise due to these lasers may be problematic, given the relatively low repetition rate (< 100 Hz) and shot-to-shot fluctuations of several per cent. For example, the mode-beating effects in Q-switched Nd:YAG lasers can cause huge shot-to-shot variations in the nonlinear optical effect. Fortunately, this mode-beating problem can be addressed by using an injection seeded Nd:YAG. Mode-locked lasers provide intense peak powers (many gigawatts) in an extremely short pulse (femtoseconds to picoseconds). These lasers typically also have high repetition rates (kHz or MHz) which is convenient for signal averaging. Owing to the inverse relationship between bandwidth and pulse duration, however, mode-locked lasers generate spectrally broad pulses that may not permit adequate resolution for the system under study. Mode-locked lasers are often used for time-domain CARS.

Although a narrow bandwidth is often preferred for high-resolution studies, some applications benefit from the use of a laser having a broad bandwidth in conjunction with multiwavelength detection. Spectra generated by wavelength scanning a narrowband laser can contain unwanted effects when working with samples or environments that change rapidly (e.g. turbulent combustion systems). On the other hand, broadband dye lasers with broad bandwidths (> 100 cm $^{-1}$) can be used with multiwavelength detection to perform single-shot CARS spectroscopy.

The following are some key properties of a laser system:

- tuning range
- linewidth
- pulse length
- pulse energy (peak power)

- coherence
- polarization
- stability and reproducibility
- practical issues (e.g. cost, maintenance, convenience).

Detection System

The primary functions of the detection system are to reject unwanted light, to measure the intensity of the output signal, and to analyse spectrally or temporally the output signal if needed. Collection optics (e.g. lenses, optical fibres), wavelength separation devices, detectors, and associated electronics are common components of the detection system.

Possible sources of unwanted light include fluorescence, Rayleigh scattering and ambient room light. A well-designed system will provide three means for rejecting this unwanted light and for minimizing potential damage to optics, slits, and detectors from intense beams of light. Spectral rejection may be accomplished using a combination of wavelength separation devices such as filters, prisms, gratings, or monochromators. Temporal rejection may be achieved using electronic gating, optical gating, or lock-in amplification if the signal is driven by pulsed or modulated lasers. Spatial filters that interrupt the input beams can be incorporated into the detection system if phase matching can cause the output beam to leave the sample at a different angle than that of the input beams.

Measurement of the intensity may be performed using a broad range of photoemissive or semiconductor detectors. Common issues to consider include wavelength sensitivity, damage or saturation threshold, linearity, and noise. Photoemissive detectors such as photomultiplier tubes are fast and sensitive in the UV and visible regions. They are, however, insensitive in the infrared region and easily damaged by high levels of light. Semiconductor photodiodes are less sensitive but more rugged, and may be used for more intense signals ($>10^7$ photons per pulse). Photoemissive and semiconductor detectors may also be used in multichannel form for multiwavelength detection. Examples include charge-coupled devices (CCDs) and photodiode arrays with or without micro-channel plate intensifiers.

If needed, spectral analysis of light from the output beam can be achieved using a simple monochromator with a multiwavelength detector (CCD or diode array). The spectral resolution is determined by the size of the monochromator, the width of the entrance slit, the density and order of the grating, and the distance between individual elements in the detector array. Fast temporal analysis may be achieved using a fast detector such as a streak camera with picosecond or sub-picosecond temporal resolution.

Most detection systems operate in one of four possible modes: single-wavelength detection, scanning detection,

multiwavelength detection, and time-resolved detection. The simplest of these, single-wavelength detection, involves the detection of light at one fixed wavelength with rejection of light at all other wavelengths. The detection system may be as simple as a narrowband dielectric filter in front of a photodetector, although the use of a monochromator allows more flexibility for control of bandwidth and selection of wavelength. Scanning detection is needed for measurement of an output beam that is changing in wavelength. It typically involves wavelength scanning of a monochromator with a photodetector, although broadband filters may be used if the change in wavelength of the output beam is small. Multiwavelength detection is required when the output beam contains multiple frequency components that form a complete spectrum. The equipment for this mode is briefly discussed in the preceding paragraph. Time-resolved detection provides temporal information when the temporal behaviour of the output beam provides information such as the response of a system to an externally controlled stimulus.

The following are some figures of merit for detectors:

- time response and resolution
- wavelength response, discrimination, and resolution
- spatial discrimination
- sensitivity
- stability and noise
- practical issues – cost, convenience
- multichannel vs single channel
- saturation and damage threshold
- linear response and dynamic range.

Techniques

Acquisition of Spectra

Spectral information may be acquired in three ways. The first method is the conventional approach where one or more of the laser field frequencies are tuned to match Raman-active resonances. The second approach is to use a broadband source that allows the spectral information to be obtained in a single shot. The third is to use a time-resolved approach, where time between the pulses is varied and the sample response is measured as a function of the delay.

Scanned CARS

In conventional frequency-domain CARS, either ω_1 or ω_2 is scanned so that $\omega_1 - \omega_2$ passes through Raman-active resonances. As the difference in frequency between these two beams is tuned to each resonance, a resonance enhancement of the nonlinear optical effect occurs, leading to a peak in the intensity of the output beam.

Figure 5 A CARS vibrational spectrum produced by monitoring the output beam intensity (at ω_4) while wavelength scanning an OPO (see **Figure 4(b)**). This spectrum shows Raman-active peaks from benzene (b), oxygen (o), nitrogen (n), and cyclohexane (c) covering a range from 681 cm^{-1} ($\lambda_{\text{OPO}} = 552\text{ nm}$) to 3098 cm^{-1} ($\lambda_{\text{OPO}} = 637\text{ nm}$). Zero frequency shift corresponds to $\lambda_{\text{OPO}} = 532\text{ nm}$.

Spectra are produced by plotting the intensity of the output beam as a function of $\omega_1 - \omega_2$.

The output beam is typically monitored using a scanning detection system because $\omega_4 = \omega_1 - \omega_2 + \omega_3$ varies as the input frequencies are varied. However, single-wavelength detection may be accomplished if ω_4 is held constant by simultaneously tuning ω_3 to compensate for the changes in $\omega_1 - \omega_2$. One way to accomplish this compensation is to let ω_1 and ω_3 be generated by an OPO idler and signal beam (see **Figure 4b**). As the OPO beams are tuned, $\omega_1 - \omega_2$ changes, but ω_2 and ω_4 remain constant. This approach also reduces the phase mismatch during a scan because the angles between the scanned beams (θ in eqn [5]) may be reduced to zero. An example of a CARS vibrational spectrum produced whilst wavelength scanning an OPO is shown in **Figure 5**.

Shot-to-shot noise in the laser system can degrade the quality of the spectra for scanned CARS. Since the signal depends on the product of three input intensities, relatively small noise in the pump laser can result in a much greater noise in the output beam intensity. This problem is especially problematic in Q-switched Nd:YAG lasers that are not injection seeded. Furthermore, shot-to-shot temporal jitter between pulses in a system that does not have a single pump laser can result in noisy spectra. Such noise problems may be corrected by simultaneously monitoring and dividing the signal by the individual pump beam intensities. Alternatively, parts of the input beams may be focused into a separate reference cell to simultaneously generate a nonresonant signal to correct for fluctuations.

Single-Shot CARS

Single-shot CARS may be accomplished by using one or more broadband lasers in addition to one or more narrowband lasers for the input beams. Each frequency element of the broadband laser(s) can independently mix with the narrowband frequency, contributing a separate

frequency element to the output beam. This approach, called multi-colour CARS, multiplex CARS, or single-shot CARS, typically uses a broadband dye laser and multiwavelength detection in order to capture simultaneously a region of a few hundred wavenumbers of a rotational and/or vibrational spectrum. For example, dual broadband CARS involves the use of a single broadband dye laser for ω_1 and ω_2 , and a fixed narrowband frequency beam for ω_3 (e.g. the pump beam for the dye laser). The resulting technique provides a relatively simple way to obtain single-shot rotational spectra in the range $0\text{--}150\text{ cm}^{-1}$. Unlike scanned CARS, the spectral resolution for this technique is often determined by the detection system.

This approach is especially useful in the analysis of gas-phase combustion and other systems where turbulence may be a problem. In the condensed phase, the range of coverage may be limited by phase matching.

Time-Resolved Nonlinear Raman

Time-domain CARS involves the use of short picosecond or femtosecond pulses to generate the nonlinear Raman signal. Up to three separately timed excitation pulses may be combined in the sample, resulting in the generation of a pulse of light called a photon echo. Measurement of size of the photon echo as a function of the delay time between pulses can be used to determine values of both the energy relaxation times T_1 and the phase relaxation times T_2 . Time resolution of several femtoseconds is possible.

Another option for performing time-resolved nonlinear Raman spectroscopy is to use a fast detector such as a streak camera. By combining short picosecond or femtosecond pulses with longer nanosecond pulses, a generated signal can be produced that evolves over time. This approach can be used to obtain simultaneously both frequency and time domain information.

Symbols

A_ω	complex pulse area
D	number of distinguishable permutations of the pairs (ω, α)
$\langle er \rangle$	expectation value of the molecular dipole operator
E_i	energy of level i
$E(t)$	electric field vector
$E_\mu(t)$	component along μ of the electric field vector
$E(\omega)$	amplitude of the Fourier component of E at frequency ω
E_ω	amplitude of the monochromatic wave at frequency ω
$E_{\omega\mu}$	component along μ of E_ω
$E_\omega(t)$	envelope of the quasi-monochromatic field at central frequency ω
$H(t)$	time-dependent total Hamiltonian
H_0	unperturbed Hamiltonian in the absence of electromagnetic fields
I_ω	intensity of the monochromatic wave at frequency ω
N	number density of molecules
n_σ	refractive index at frequency ω_σ
$P(t)$	macroscopic polarization vector
$P^{(n)}$	n -th order term in the series expansion of P in powers of the applied field
$P_\mu^{(3)}$	component along μ of $P^{(3)}$
$P(\omega)$	amplitude of the Fourier component of P at frequency ω
$P_\mu^{(3)}(\omega)$	amplitude of the monochromatic polarization wave at frequency ω
$P_\omega^{(3)}(t)$	envelope of the quasi-monochromatic third-order polarization component at central frequency ω
$P_{\omega\mu}^{(3)}$	component along μ of $P_\omega^{(3)}$
$R^{(n)}(\tau_1, \tau_2, \tau_3)$	third-order nonlinear response function tensor
$R_{\mu\alpha\beta\gamma}^{(3)}(\tau_1, \tau_2, \tau_3)$	component of $R^{(3)}$ with Cartesian index $\mu\alpha\beta\gamma$

R_{ab}^{μ}	component along μ of the transition dipole matrix element for transitions from a to b
T_1	population relaxation characteristic time
T_2	phase relaxation characteristic time
$V(t)$	interaction operator
$(\alpha(\omega))_{gf}$	Raman scattering tensor for transitions from state g to state f
$(\alpha_{\delta\epsilon}(\omega))_{gf}$	component $\delta\epsilon$ of the Raman scattering tensor
Γ	relaxation matrix
Γ_{ij}	matrix element of Γ
$\Gamma_{ij}^{\text{proper}}$	pure dephasing term associated with element ρ_{ij} of the density matrix
Δk	phase mismatch vector
$\rho(t)$	density matrix of the material system
$\rho_{ij}(t)$	matrix element of ρ_k
$\rho^{(3)}(t)$	third-order term in the development of the matrix density in power series of the interaction
τ_p	characteristic time of the radiation (it represents the period of the fastest amplitude change in a laser pulse)
$\Phi_{-\omega_\sigma; \omega_0 \omega_p - \omega_s}^{(3)}(\tau_1, \tau_2, \tau_3)$	third-order nonlinear envelope response function
$\chi^{(n)}(-\omega_\sigma; \omega_1 \omega_2 \omega_3)$	n th-order nonlinear susceptibility tensor
$\chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_1 \omega_2 \omega_3)$	component of $\chi^{(3)}$ with Cartesian index $\mu\alpha\beta\gamma$
$\chi^{(3)\text{NR}}$	nonresonant part of the third-order nonlinear susceptibility
$\chi'^{(3)\text{R}}$	real resonant part of the third-order nonlinear susceptibility
$\chi''^{(3)\text{R}}$	imaginary resonant part of the third-order nonlinear susceptibility
ω	frequency of the radiation, $E = \hbar\omega$
ω_R	frequency corresponding to a Raman transition

ω_{ij}	$(E_i - E_j)/\hbar$ = frequency corresponding to the energy gap for levels i and j
Ω_{ab}	$\omega_{ab} - i\Gamma_{ab}$ = compact complex notation for detuning and relaxation
$\hbar$	Planck constant/ 2π

Introduction

In a typical spontaneous Raman experiment, an incident, nonresonant photon of energy $\hbar\omega_P$ interacts with the molecule and is scattered into a photon of energy $\hbar(\omega_P \pm \omega_R)$ where ω_R is the frequency of a vibrational mode. The molecule undergoes a transition that balances the gain or loss of field energy. The spectroscopic information is extracted by measuring the energy change of the scattered photon.

From a classical point of view, the molecule is polarized by its interaction with the input field at ω_P and an oscillating dipole at frequency ω_P is induced. As the molecular polarizability itself is modulated by inter-nuclear motion at frequency ω_R , lateral bands appear at combination frequencies. The molecular dipole oscillating at $\omega_P \pm \omega_R$ radiates a field at these frequencies. Even with a coherent input field, as provided by lasers, the output field is incoherent because the phases of individual scatterers are not correlated.

In a typical nonlinear Raman experiment the molecule interacts with two strong coherent fields at frequencies ω_P (pump) and ω_S (Stokes). As we will see below, for a strong field the response of the system is nonlinear and the molecular polarizability at a given frequency is periodically modulated at the driving frequencies and at new frequencies that are linear combinations of these $2\omega_P$, $2\omega_S$, $\omega_P \pm \omega_S$, If we focus on the oscillating polarizability component at $\omega_P - \omega_S$, the interaction with either of the input fields or with a third input field at ω_0 gives rise as before to a component of the induced dipole at a combination frequency, such as $\omega_P + (\omega_P - \omega_S) = \omega_{AS}$, $\omega_P - (\omega_P - \omega_S) = \omega_S$, $\omega_0 + (\omega_P - \omega_S)$, whose amplitude depends on intrinsic molecular properties and on the product of three field amplitudes. AS and S refer to anti-Stokes and Stokes frequencies respectively. The input fields being temporal and spatially coherent, there is a definite phase relationship between driven dipole oscillations of different molecules in the interaction volume, giving rise to a coherent macroscopic polarization in the medium.

The created polarization acts as a source and a new coherent field at frequency ω_σ grows to some extent or, if $\omega_\sigma = \omega_P$, ω_S or ω_0 , the corresponding amplitude

increases or decreases depending upon the relative field-polarization phase.

The above behaviour is quite general and will be observed for any molecule and frequency combination, provided that some macroscopic symmetry requirements are met. The interaction just described is a four-wave process: a macroscopic polarization at a signal frequency ω_σ builds up through a nonlinear frequency mixing of three frequency components of the electromagnetic field. In a general $(n+1)$ -wave process, n frequency components are mixed to produce an oscillating polarization at $\omega_\sigma = \pm(\omega_1 \pm \omega_2 \pm \omega_3 \pm \dots \pm \omega_n)$. The magnitude of the nonlinear polarization depends on the product of n field amplitudes and an n th-order nonlinear susceptibility $\chi^{(n)}(\omega_\sigma; \omega_1, \omega_2, \dots, \omega_n)$, which is a material property.

The connection of this nonlinear optical effect with spectroscopy lies in the fact that $\chi^{(n)}$, and hence the signal strength, will be enhanced whenever a linear combination of a subset of $m \leq n$ frequency components approaches the energy difference of two molecular states of proper symmetry. This m -photon resonant enhancement – which can in principle be observed even in the absence of real transitions, as will be the case for states with no thermal population – has been exploited to develop a number of nonlinear spectroscopic techniques that differ in order n , order of the used resonance m , number of colours (i.e. different actual laser fields that provide the frequency components), spectral and temporal resolution and the actual method used to detect the resonances by monitoring either the power generated at ω_σ or the change in amplitude, polarization or phase at some of the input frequencies.

The simplest m -photon resonance is obtained for $m=2$ when $\Omega_{fg} = (E_f - E_g)/\hbar \simeq \omega_1 \pm \omega_2$. If we consider ω_1 and ω_2 to be typical optical frequencies, the $+$ sign corresponds to two vibronic states g and f , from different electronic states, in resonance with $2\omega_1$, $2\omega_2$ or $\omega_1 + \omega_2$: two-photon absorption-like resonance (TPA).

Most nonlinear Raman techniques correspond to the $-$ sign above: $\Omega_{fg} \simeq \omega_P - \omega_S$ (Raman-like resonance), where frequency subscripts have been converted to the usual Raman convention. These resonances can contribute to enhance n th-order processes for $n \geq 2$. For isotropic media, all even-order susceptibilities vanish and Raman techniques involve 3rd, 5th, 7th, ... order nonlinear susceptibilities. The ordering comes from a perturbative development of the field-molecule interaction and, as far as the perturbative approach can be applied, successive orders correspond to much smaller terms. Hence we can study the main spectroscopic features with only the lowest-order nonvanishing term, and most nonlinear Raman techniques are 3rd-order four-wave processes, which will constitute the main topic in this article. These techniques are indeed readily implemented with present

laser technology in a variety of media, including gases at low pressure.

We can perform Raman spectroscopy by monitoring different properties of the macroscopic field as we scan ω_p

or ω_s in such a way that $\omega_p - \omega_s \simeq \Omega_{fg} \equiv \omega_R$, leading to several techniques that have usually been identified by acronyms. The energy level diagrams for the main nonlinear Raman techniques are depicted in **Figure 1**.

Figure 1 Energy level diagrams for nonlinear Raman spectroscopic techniques. The input fields are shown as arrows pointing upwards for positive frequency (downwards for negative) in the arguments of the nonlinear susceptibility, and the output field as a dashed arrow, which must close the diagram. Schematic molecular energy levels are represented to show the main Raman resonance and additional one-photon resonances. Horizontal position does not imply time ordering. The energy balance involves the field and the material excitation in different ways for different techniques. In pure nonresonant processes, the energy of created photons balances that of those destroyed. In SRL and SRG, each scattering event leads to an excited molecule. In Raman-resonant FWM and CARS, the energy of destroyed photons is shared among material excitation and created photons depending on the relative magnitude of the imaginary and real parts of the nonlinear susceptibility.

With only two colours we can monitor the intensity of the generated beam at the anti-Stokes frequency $\omega_{AS} = \omega_P + \omega_R$ (coherent anti-Stokes Raman spectroscopy, CARS) or the Stokes frequency respect to ω_S , $\omega_{CSRS} = \omega_S - \omega_R$ (coherent Stokes Raman spectroscopy, CSRS). Alternatively, we can monitor the intensity increase at ω_S (stimulated Raman gain spectroscopy, SRG) or the intensity decrease at ω_P (stimulated Raman loss, SRL, also known as inverse Raman spectroscopy, IRS). If we focus on the polarization of the created field or the change in polarization state of input fields, we arrive at different polarization variants of the above techniques, such as polarization CARS, CARS ellipsometry or Raman-induced Kerr effect (RIKES). The input frequencies can be tuned to match additional one-photon resonances that can enhance the signal by several orders of magnitude, leading to techniques such as resonance CARS. A third colour ω_0 can be used for different purposes such as fine tuning of additional one-photon resonances or shifting the signal frequency $\omega_\sigma = \omega_0 + \omega_R$ to a more convenient region; this expands the possibilities, leading to Raman resonant four-wave mixing (FWM). The different choices of input and signal beams are collected in **Table 1** along with the names of the associated nonlinear Raman spectroscopic techniques.

The spectroscopic use of three-photon resonances has been demonstrated, although these usually require additional enhancement through one-photon electronic resonance, or the use of condensed media. Closely related to Raman spectroscopy is coherent hyper-Raman scattering (see **Figure 1**), the stimulated analogue of the spontaneous hyper-Raman effect, for which a three-photon resonant enhancement $\Omega_{fg} \simeq 2\omega_1 - \omega_2$ can be detected in $\chi^{(5)}$ in a six-wave process, for example by monitoring the intensity of the generated field at $\omega_\sigma = 4\omega_1 - \omega_2 \simeq 2\omega_1 + \omega_R$. We will not explicitly consider these higher-order resonances in the following, but the theory involved closely follows that for the simplest two-photon resonant four-wave case.

From a fully quantum-mechanical view, the system (matter + field) undergoes a transition from an initial state $|n_P = n, n_S = 0, g\rangle$, for which the input field has n photons, the output field is at the vacuum state and the molecule in an internal state g to a final state $|n_P = n - 1, n_S = 1, f\rangle$. Owing to the low Raman scattering cross section, the probability of finding one scattered photon within the interaction region at the time of the next scattering event is vanishingly small at low input intensity. As a consequence, the initial state of the output mode is always the vacuum state and the number of scattered photons is linearly dependent on the number of photons in the input field alone. At high input intensity or in the presence of a second external field at ω_S , $n_S \neq 0$ and the matrix element depends on the product of $n_P \times n_S$. Therefore, spontaneous and nonlinear Raman are closely

connected. In fact, the spontaneous Raman effect cannot be considered among linear optical phenomena such as absorption, diffraction or stimulated emission because the scattered field has a different frequency.

The dependence of the spatial, spectral and temporal signal properties on those of the input beams, along with the broad range of lasers available, opens many possibilities ranging from high-resolution studies of gases at Doppler-limited resolution using narrow-bandwidth lasers to high-temporal-resolution studies of intramolecular and intermolecular dynamics and relaxation processes at the femtosecond scale in condensed media. Although the underlying theory is essentially the same, high-resolution studies are better described in the frequency domain, looking at the Raman resonances in the nonlinear susceptibility of the medium, allowing for interpretation of line position, intensity and (with the inclusion of relaxation terms) line width. Broadband ultrashort pulses lead to an impulse response, where the molecule evolves freely after the sudden excitation involving many states and is probed at later times. This situation is better described in the time domain, looking at the time evolution of the nonlinear response function, which shows relaxation and dynamic processes, directly and still contains information about the spectrum in the form of oscillations or beating among different excited modes. Midway between these limits, lasers with small bandwidth and short duration can be used to excite a selected set of molecular levels and study their evolution.

Theory

The theory relating first principles to practical signal expressions for an arbitrary material system can be considered to be well understood. We present here a sketch of its main aspects, indicating the approximations needed and its scope. Our goal is to give a practical signal expression in terms of Raman scattering tensor components, field intensities and polarizations. Our model system is an isotropic medium composed of polarizable units, small compared with the wavelength, interacting only through their coupling to a common thermal bath, such as a gas or dilute solution, in the presence of a superposition of quasi-monochromatic ($\delta\omega_i \ll \omega_i$) laser pulses.

Nonlinear interaction can be studied on a full quantum basis by expressing the Hamiltonian in terms of quantum operators for the material and the radiation degrees of freedom, but the most fruitful treatment has been the semiclassical approach in which the electric field operator is replaced by its expectation value and considered as a function, though quantum operators are used for the material. Only electric dipole polarization will be addressed.

Table 1 Nonlinear Raman spectroscopic techniques

	FWM	CARS	RIKES
Name	Four-wave mixing	Coherent anti-Stokes Raman spectroscopy	Raman-induced Kerr effect
Monitored effect	Intensity at $\omega_\sigma = \omega_0 + \omega_R$	Intensity at $\omega_{\text{anti-Stokes}} = \omega_P + \omega_R$	Intensity at ω_S polarized $\perp$
Input/output field	$\omega_0, \omega_P, \omega_S/\omega_0 + \omega_R$	$\omega_P, \omega_S/\omega_A$	$\omega_P, \omega_S/\omega_S$
Input/output polarization	All possibilities with paired Cartesian index	$E_{\omega_P \times^N} E_{-\omega_S \times^N}/E_{\omega_A \times^N} E_{\omega_P \times^N}/E_{\omega_A \times^N}$	E_{ω_P} circular, $E_{\omega_S \times^N}/E_{\omega_S \times^N}$
Effective susceptibility	$\chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0 \omega_0 - \omega_S) = \chi_{\mu\alpha\beta\gamma}^{(3)NR} + \frac{1}{6\epsilon_0 \hbar} \times \sum_{g,l} (N_g - N_l) \alpha_{xi\mu} \alpha_{x\beta} \left(\frac{\Delta_{lg}}{\Delta_{lg}^2 + \Gamma_{lg}^2} + i \frac{\Gamma_{lg}}{\Delta_{lg}^2 + \Gamma_{lg}^2} \right)$	$\chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0 \omega_P - \omega_S) = \chi_{\mu\alpha\beta\gamma}^{(3)NR} + \frac{1}{3\epsilon_0 \hbar} \times \sum_{g,l} (N_g - N_l) \alpha_{xx}^2 \left(\frac{\Delta_{lg}}{\Delta_{lg}^2 + \Gamma_{lg}^2} + i \frac{\Gamma_{lg}}{\Delta_{lg}^2 + \Gamma_{lg}^2} \right)$	$\chi_{\text{eff}}^{(3)}(-\omega_S; \omega_P - \omega_P \omega_S) = \chi_{\text{eff}}^{(3)}(\chi_{yxxy} - \chi_{xyxx}) \approx \frac{i}{2} \left(\chi_{yxxy}^{(3)} - \chi_{xyxx}^{(3)} \right) \approx \frac{i}{2} \left(\chi_{yxxy}^{(3)R} - \chi_{xyxx}^{(3)R} \right)$
Signal ^a	$I_{\omega_\sigma} = \frac{9}{4} \frac{\omega_\sigma^2}{\epsilon_0^2 c^4} n_P n_0 n_P n_S \chi_{\mu\alpha\beta\gamma}^{(3)} ^2 I_{\omega_0} I_{\omega_P} I_{\omega_S} L^2 \text{sinc}^2(\Delta k L/2)$	$I_{\omega_A}(L) = \frac{9}{16} \frac{\omega_A^2}{\epsilon_0^2 c^4 n_A n_P^2 n_S} \chi_{\lambda xxx}^{(3)} ^2 I_{\omega_P}^2(0) I_{\omega_S}(0) L^2 \times \text{sinc}^2(\Delta k L/2)$	$\propto \chi_{\text{eff}}^{(3)RIKES}(-\omega_S; \omega_P - \omega_P \omega_S) ^2 I_P^2 / s$

^aSignal expression for plane monochromatic input waves. L is the interaction length.

Owing to the coherence, we need to consider the macroscopic evolution of the field in a medium that shows a macroscopic polarization induced by the field-matter interaction. This will be done in three steps. First, the polarization induced by an arbitrary field will be calculated and expanded in power series in the field, the coefficients of the expansion being the material susceptibilities $\chi^{(n)}$ (frequency domain) or response function $\mathbf{R}^{(n)}$ (time domain) of n th-order. Nonlinear Raman effects appear at third order in this expansion. Second, the perturbation theory derivation of the third-order nonlinear susceptibility $\chi^{(3)}$ in terms of molecular eigenstates and transition moments will be outlined, leading to a connection with the spontaneous Raman scattering tensor components. Last, the interaction of the initial field distribution with the created polarization will be evaluated and the signal expression obtained for the relevant techniques of Table 1.

Macroscopic Nonlinear Polarization

We consider a unit volume that contains many molecules but is small compared to the wavelength. The electric field can be considered uniform inside this volume. By expanding the polarization at a given time in power series in the field, we obtain for a given point:

$$\mathbf{P}(t) = \mathbf{P}^{(0)}(t) + \mathbf{P}^{(1)}(t) + \mathbf{P}^{(2)}(t) + \mathbf{P}^{(3)}(t) + \dots \quad [1]$$

where $\mathbf{P}^{(0)}$ stands for the static polarization, $\mathbf{P}^{(1)}$ is linear in the field, $\mathbf{P}^{(2)}$ quadratic and so on (bold typefaces represent a vector, tensor or matrix magnitude).

The next approximation is to consider only the *local response*: the polarization at the point $\mathbf{r}$ depends only on the field at this point. In condensed media, the local field sensed by the molecule includes the depolarizing effect of the surrounding molecules, and it does depend on the field values at different points. In an anisotropic medium the material response shows *spatial dispersion* and is sensitive to both the frequency and the wave vector of the driving fields.

Nonlinear Raman processes are governed by the third-order polarization, which can be expressed in the time domain, for a generic electric field, in component form:

$$P_{\mu}^{(3)}(t) = \epsilon_0 \int_{-\infty}^{\infty} d\tau_1 \int_{-\infty}^{\infty} d\tau_2 \int_{-\infty}^{\infty} d\tau_3 \times R_{\mu\alpha\beta\gamma}(\tau_1, \tau_2, \tau_3) E_{\alpha}(t - \tau_1) E_{\beta}(t - \tau_2) E_{\gamma}(t - \tau_3) \quad [2]$$

where summation over repeated indices is assumed.

$\mathbf{R}^{(3)}(\tau_1, \tau_2, \tau_3)$ is a fourth-order tensor ($\mathbf{R}^{(n)}$ has rank $n + 1$) of components $R_{\mu\alpha\beta\gamma}(\tau_1, \tau_2, \tau_3)$ where $\mu\alpha\beta\gamma$ represent Cartesian coordinates describing the field

polarization. It is a real function of n time variables (because $\mathbf{E}$ and $\mathbf{P}$ are physical observables) and vanishes whenever any of its time arguments are negative because the polarization at time t cannot depend on the field values at later times. Owing to the implicit summation, the above equation is invariant to any permutation of the pairs $(\alpha, \tau_1), (\beta, \tau_2)$ etc. (intrinsic permutation symmetry).

To study narrow resonances, the frequency domain allows for a better description of the material response in terms of susceptibilities. To obtain the corresponding expressions we take the Fourier transform of $\mathbf{E}(t)$ and $\mathbf{P}(t)$.

$$\begin{aligned} E(t) &= \int_{-\infty}^{\infty} d\omega E(\omega) \exp(-i\omega t) \\ E(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau E(\tau) \exp(i\omega\tau) \\ P(t) &= \int_{-\infty}^{\infty} d\omega P(\omega) \exp(-i\omega t) \\ P(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau P(\tau) \exp(i\omega\tau) \end{aligned} \quad [3]$$

By substituting eqn [3] into eqn [2] and rearranging, we arrive at

$$\begin{aligned} P_{\mu}^{(3)}(\omega_{\sigma}) &= \epsilon_0 \int_{-\infty}^{\infty} d\omega_1 \int_{-\infty}^{\infty} d\omega_2 \int_{-\infty}^{\infty} d\omega_3 \\ &\times \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_{\sigma}; \omega_1 \omega_2 \omega_3) E_{\alpha}(\omega_1) E_{\beta}(\omega_2) E_{\gamma}(\omega_3) \delta(\omega - \omega_{\sigma}) \end{aligned} \quad [4]$$

where $\omega_{\sigma} = \omega_1 + \omega_2 + \omega_3$, and the third-order nonlinear susceptibility $\chi_{\mu\alpha\beta\gamma}^{(3)}$ is defined by

$$\begin{aligned} \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_{\sigma}; \omega_1 \omega_2 \omega_3) &= \int_{-\infty}^{\infty} d\tau_1 \int_{-\infty}^{\infty} d\tau_2 \int_{-\infty}^{\infty} d\tau_3 \\ &\times R_{\mu\alpha\beta\gamma}^{(3)}(\tau_1 \tau_2 \tau_3) \exp(i \sum \omega_i \tau_i) \end{aligned} \quad [5]$$

$\chi^{(3)}$ is a field- and time-independent fourth-rank tensor, and a function of three frequency arguments. Its general properties can be derived from that of the nonlinear response: $E(\omega)$ and $\mathbf{P}^{(3)}(\omega)$ include both positive and negative frequencies, related by the conditions $E(-\omega) = E^*(\omega)$, $\mathbf{P}(-\omega) = \mathbf{P}^*(\omega)$. The reality condition of $\mathbf{R}^{(n)}$ implies that $[\chi^{(3)}(-\omega_{\sigma}; \omega_1 \omega_2 \omega_3)]^* = \chi^{(3)}(\omega_{\sigma}; -\omega_1 -\omega_2 -\omega_3)$, $\chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_{\sigma}; \omega_1 \omega_2 \omega_3)$ is invariant under the permutation of the pairs $(\alpha, \omega_1), (\beta, \omega_2)$.

The integration in eqn [4] considers the existence of several frequency combinations matching the condition $\omega_{\sigma} = \sum_j \omega_j$ within the bandwidth of the applied field.

A single laser whose bandwidth is large enough to include frequency components that match $\omega_a - \omega_b = \omega_R$ can drive the nonlinear response. However, more frequently the laser bandwidth is smaller than ω_R and different beams with distinct centre frequencies are needed to match the Raman resonance. Let us now consider a field composed of a superposition of quasi-monochromatic beams, i.e. the amplitude at a carrier frequency is modulated by a complex envelope that defines its spectral shape. The central frequencies are chosen to match the Raman resonant four-wave mixing scheme (see **Table 1**), which can be later adapted to other colour choices. Three laser beams are present of frequencies ω_0 , ω_P , ω_S , with $\omega_P - \omega_S = \omega_R$ as the only resonant frequency combination.

The field can be expressed as

$$E(t) = \sum_{\omega_j = \omega_0, \omega_P, \omega_S} \frac{1}{2} [E_{\omega_j}(t) \exp(-i\omega_j t) + E_{-\omega_j}(t) \exp(i\omega_j t)] \quad [6]$$

The envelope $E_{\omega_j}(t)$ is now time-dependent, and contains both amplitude and phase information, thus defining the spectrum (centred at ω_j) of each field. It is implicit in the above considerations that $E_{\omega_j}(t)$ changes smoothly in the timescale of $(\omega_j)^{-1}$. By substituting eqn [6] into eqn [4], we find that $\mathbf{P}^{(3)}(t)$ can be recast as a sum of quasi-monochromatic components at central frequency ω_σ . The envelope $\mathbf{P}_{\omega_\sigma}^{(3)}(t)$ will vanish due to the fast oscillating exponential factors except when ω_σ is close to any linear combination of three frequencies chosen among the input frequencies, leading to

$$\mathbf{P}^{(3)}(t) = \sum_{\omega_\sigma} \frac{1}{2} [\mathbf{P}_{\omega_\sigma}^{(3)}(t) \exp(-i\omega_\sigma t) + \mathbf{P}_{-\omega_\sigma}^{(3)}(t) \exp(i\omega_\sigma t)] \quad [7]$$

Only combinations including $\pm(\omega_P - \omega_S)$ will show resonant enhancement. Among these, we are interested in the term that oscillates at a centre frequency $\omega_\sigma = \omega_0 + \omega_P - \omega_S$, which corresponds to a field ω_0 being scattered into an output field $\omega_0 + \omega_R$ due to the driving effect of the resonant pair ω_P, ω_S . This term is

$$\begin{aligned} \mathbf{P}_{\omega_\sigma}^{(3)}(t) = & \epsilon_0 \frac{D}{4} \int_{-\infty}^{\infty} d\tau_1 \int_{-\infty}^{\infty} d\tau_2 \int_{-\infty}^{\infty} d\tau_3 \\ & \times \Phi_{-\omega_\sigma; \omega_0 \omega_P - \omega_S}^{(3)}(t - \tau_1, t - \tau_2, t - \tau_3) \\ & \times E_{\omega_0}(\tau_1) E_{\omega_P}(\tau_2) E_{\omega_S}^*(\tau_3) \end{aligned} \quad [8]$$

where $\Phi^{(3)}(t - \tau_1, t - \tau_2, t - \tau_3) = \mathbf{R}^{(3)}(t - \tau_1, t - \tau_2, t - \tau_3) \exp(i\sum_j \omega_j \tau_j)$ is an *envelope response function* that relates the envelope of the third-order polarization at frequency ω_σ with the envelopes of the fields when their

central frequency is tuned to the values given by the subscripts of $\Phi^{(3)}$. The relationship between $\chi^{(3)}$ and $\Phi^{(3)}$ is:

$$\begin{aligned} \chi^{(3)}(-\omega_\sigma; \omega_0 \omega_P - \omega_S) = & \int_{-\infty}^{\infty} d\tau_1 \int_{-\infty}^{\infty} d\tau_2 \int_{-\infty}^{\infty} d\tau_3 \\ & \times \Phi_{-\omega_\sigma; \omega_0 \omega_P - \omega_S}^{(3)}(\tau_1, \tau_2, \tau_3) \end{aligned} \quad [9]$$

The D factor above comes from the identification of terms in the summation that are identical owing to the intrinsic permutation symmetry. We must now compare the characteristic time scale of the material T_1 (population relaxation) and T_2 (phase relaxation) with that of the laser pulse τ_p , taken as the period of the fastest amplitude change in the field (similar to the pulse duration for a smooth, narrow-bandwidth pulse, but close to the inverse of the full bandwidth for a multimode laser).

For $\tau_p \ll T_2$ each pulse appears to the system as a δ impulsion at fixed time t_i , $A E_{\omega_a}(t) = A_{\omega_a} \delta(t - t_i)$, where A_{ω_a} is the complex pulse area. The polarization is

$$\begin{aligned} \mathbf{P}_{\omega_\sigma}^{(3)}(t) = & \epsilon_0 \frac{D}{4} \Phi_{-\omega_\sigma; \omega_0 \omega_P - \omega_S}^{(3)}(t - t_0, t - t_P, t - t_S) \\ & A_{\omega_0} A_{\omega_P} A_{\omega_S}^* \end{aligned} \quad [10]$$

$\Phi^{(3)}$ can now be directly measured by changing the times t_i at which the pulses are applied. A typical implementation of this scheme is to excite a Raman mode by applying ω_P and ω_S simultaneously at $t=0$ and provide some variable delay for the response to evolve before applying the field at ω_0 that is scattered into the signal field ω_σ .

On the other hand, for $\tau_p \gg T_2$ the macroscopic polarization relaxes very fast, the system loses memory of previous field values, and $\mathbf{P}_{\omega_\sigma}^{(3)}(t)$ follows adiabatically the field envelope, leading to

$$\begin{aligned} \mathbf{P}_{\omega_\sigma}^{(3)}(t) = & \epsilon_0 \frac{D}{4} \chi^{(3)}(-\omega_\sigma; \omega_0 \omega_P - \omega_S) \\ & \times E_{\omega_0}(t) E_{\omega_P}(t) E_{\omega_S}^*(t) \end{aligned} \quad [11]$$

This expression is the starting point for the vast majority of nonlinear Raman experiments. One special case that enters into this category is CW experiments with monochromatic waves ($\tau_p \rightarrow \infty$ and the amplitudes of incoming fields and nonlinear polarization become constant). The corresponding expression is

$$\begin{aligned} \mathbf{P}_{\omega_\sigma \mu}^{(3)} = & 2^{1-n} \epsilon_0 D \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0 \omega_P - \omega_S) \\ & \times E_{\omega_0 \alpha} E_{\omega_P \beta} E_{\omega_S \gamma}^* \end{aligned} \quad [12]$$

where individual vector and tensor components are used. D is the number of distinguishable permutations; thus $D=6$ for processes involving three different input frequencies but $D=3$ for two-colour processes (i.e. $\omega_0 = \omega_P$

or $\omega_0 = \omega_S$), which necessarily include two identical frequency arguments, whose permutation does not produce a distinguishable term. In this context ω_j and $-\omega_j$ must be considered different. The 2^{1-n} factor is linked to the $\frac{1}{2}$ factors appearing in eqns[6] and [7].

Although the order of frequencies in $\chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0\omega_P - \omega_S)$ has no special meaning itself, owing to the intrinsic permutation symmetry, we will keep it fixed (Raman convention), using ω_P and $-\omega_S$ as second and third arguments. Besides the intrinsic permutation symmetry, the medium macroscopic symmetry imposes further restrictions on the tensor index of nonvanishing, independent components $\chi_{\mu\alpha\beta\gamma}^{(3)}$. A very important result is that the n th-order susceptibility vanishes for even n in media showing inversion symmetry and $\chi^{(3)}$ contributes the lowest-order nonlinearity. For isotropic media, it can be shown that $\chi_{\mu\alpha\beta\gamma}^{(3)}$ vanishes if some Cartesian index appears an odd number of times in the subscript.

The symmetry properties of $\chi_{\mu\alpha\beta\gamma}^{(3)}$ in any medium can be established considering that it transforms as a fourth-rank polar tensor under the macroscopic symmetry operations. The symmetry of the microscopic polarizable units can be used to simplify the microscopic expression of $\chi_{\mu\alpha\beta\gamma}^{(3)}$.

Microscopic Origin of the Nonlinear Raman Susceptibility

We must now relate $\chi^{(3)}$ to molecular eigenstates and transition moments. This can be accomplished through standard quantum-mechanical perturbation methods. Only a sketch of the steps involved will be given here.

The microscopic origin of the nonlinear response is the distortion induced in the molecular charge distribution due to the electrical field. The presence of a microscopic dipole produces a macroscopic polarization in the unit volume $\mathbf{P} = N\langle\epsilon\mathbf{r}\rangle$, where N is the number density of polarizable units and $\langle\epsilon\mathbf{r}\rangle$ the expectation value of the dipole moment induced in each unit. In order to evaluate $\langle\epsilon\mathbf{r}\rangle$ we will use the density matrix formalism, because it is the easiest way to relate microscopic properties to macroscopic ones and to cope with macroscopic coherence effects. In the absence of fields, the medium is supposed to be described by an unperturbed Hamiltonian $\mathbf{H}_0$ and to be at equilibrium. When the fields are applied, the field-matter interaction contributes a time-dependent term $V(t) = -E(t)\mathbf{P}(t)$ to the global energy. The evolution of the system under this perturbation can be described through the equation of motion of the density operator:

$$i\hbar \frac{\partial \rho(t)}{\partial t} = [\mathbf{H}(t), \rho(t)] - i\hbar \Gamma \quad [13]$$

where $\mathbf{H}(t) = \mathbf{H}_0 + V(t)$ and the term $i\hbar \Gamma$ is introduced to include relaxation. The evolution of the matrix density elements is given by:

Diagonal elements :

$$i\hbar \frac{\partial \rho_{ii}(t)}{\partial t} = [V(t), \rho(t)]_{ii} - i\hbar \Gamma_{ii} \rho_{ii}(t) \quad [14]$$

NonDiagonal elements :

$$i\hbar \frac{\partial \rho_{ij}(t)}{\partial t} = [V(t), \rho(t)] + \hbar \rho_{ij}(t)(\omega_{ij} - i\Gamma_{ij})$$

where $\omega_{ij} = (E_i - E_j)/\hbar$ and $\Gamma_{ij} = \frac{1}{2}(\Gamma_{ii} + \Gamma_{jj}) + \Gamma_{ij}^{\text{proper}}$, Γ_{ij} being the homogeneous width of level i . $\Gamma_{ij}^{\text{proper}}$ includes the effect of dephasing processes that destroy the coherence between states i and j without altering their populations. Once we solve eqn [14] for $\rho_{ij}(t)$, the dipole moment can be calculated as $\langle\epsilon\mathbf{r}\rangle = e\text{Tr}(\rho(t)\mathbf{r})$.

Diagonal elements $\rho_{ii}(t)$ represent the fractional population of state i . Equation [14] shows that the population factors change from their initial values owing to the perturbation, while the energy relaxation mechanisms tend to restore them to the equilibrium distribution with a rate constant $\Gamma_{ii} \sim 1/T_1$.

Nondiagonal terms in eqn [14] produce a macroscopic polarization; $\rho_{ij}(t)$ departs from zero at equilibrium and includes an oscillatory term at the frequency ω_{ij} . The existence of a nondiagonal term $\rho_{ij}(t) \neq 0$ is linked to the creation of a coherent superposition of states i and j due to the perturbation. This coherence is broken through the interaction with the molecules of the bath, with a rate constant of the order of $\Gamma_{ij} = 1/T_2$. Usually this dephasing is much faster than the energy relaxation and $T_2 \ll T_1$.

Two distinct strategies exist for solving eqn [13]. The best-suited to our previous treatment starts by expanding the density matrix in a power series in the perturbation. By identifying terms we arrive at

$$\mathbf{P}^{(3)}(t) = Ne \text{Tr}(\rho^{(3)}(t)\mathbf{r}) \quad [15]$$

from which we can evaluate $\mathbf{P}^{(3)}(t)$ once we have obtained $\rho(t)$ iteratively, after expanding ρ in a basis of eigenstates of $\mathbf{H}_0$. In dense media local field factors must be included to relate the microscopic field at the molecule site to the macroscopic field of eqn [2].

This approach correctly describes the nonresonant nonlinear response and, with the inclusion of decay terms, allows treatment of Raman resonances as long as the density matrix remains close to its equilibrium value.

In the case of strong resonance, i.e. high-intensity fields closely tuned to narrow transitions, the perturbative series does not converge and this approach will fail. An alternative solution uses a simplified two-level or three-level atom model, along with effective multiphoton operators, and solves eqn [14] without using perturbation techniques. The result is a field-dependent *effective* susceptibility,

which can describe population transfer and saturation effects. It can be related to $\chi^{(n)}$ by including correction factors that are a function of the amplitude, the transition moments and the detuning from exact resonance.

The final result for the perturbative approach is given without proof. Using a time-ordered, double diagrammatic technique, it can be shown that $\chi^{(3)}$ includes a sum of 48 terms, each corresponding to a diagram that specifies a time-ordered sequence of individual interactions. Quantum interference among these paths leads to a partial cancellation whenever proper dephasing is not relevant.

Among the remaining 24 terms, we select those with Raman-resonant denominators. The other terms can be considered a weakly dispersive nonresonant background for the Raman process. Typical resonant and nonresonant terms are shown in **Table 2**.

Table 2 Some terms in the microscopic expression of the third-order nonlinear susceptibility for Raman resonance

$$\begin{aligned} \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0\omega_P - \omega_S) &= \frac{N}{6\epsilon_0\hbar^3} \sum_{gkij} \rho_{gg}^{(0)} \\ &\times \left\{ \frac{1}{[\Omega_{ig} - (\omega_P - \omega_S)](\Omega_{kg} + \omega_S)} \right. \\ &\times \left(\frac{(R_{gk})_\gamma (R_{kf})_\beta (R_{ij})_\alpha (R_{jg})_\mu}{\Omega_{ig} - \omega_\sigma} + \frac{(R_{gk})_\gamma (R_{kf})_\beta (R_{ij})_\alpha (R_{jg})_\mu}{\Omega_{ig}^* + \omega_0} \right) \\ &+ \frac{1}{[\Omega_{ig} - (\omega_P - \omega_S)](\Omega_{kg} - \omega_P)} \\ &\times \left(\frac{(R_{gk})_\beta (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\mu}{\Omega_{ig} - \omega_\sigma} + \frac{(R_{gk})_\beta (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\mu}{\Omega_{ig}^* + \omega_0} \right) \\ &+ \text{other resonant terms}^a \\ &+ \frac{1}{[\Omega_{ig}^* + (\omega_0 + \omega_P)](\Omega_{ig}^* + \omega_P)} \\ &\times \left(\frac{(R_{gk})_\mu (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\beta}{\Omega_{kg} + \omega_\sigma} + \frac{(R_{gk})_\mu (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\beta}{\Omega_{kg} + \omega_S} \right) \\ &+ \frac{1}{[\Omega_{ig}^* + (\omega_0 + \omega_P)](\Omega_{ig}^* + \omega_0)} \\ &\times \left(\frac{(R_{gk})_\mu (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\beta}{\Omega_{kg} + \omega_\sigma} + \frac{(R_{gk})_\mu (R_{kf})_\gamma (R_{ij})_\alpha (R_{jg})_\beta}{\Omega_{kg} + \omega_S} \right) \\ &\left. + \text{other nonresonant terms}^b \right\} \\ \Omega_{ab} &= (E_a - E_b)/\hbar - i\Gamma_{ab} \end{aligned}$$

$(R_{ab})_\mu$ = component along μ of the transition dipole matrix element $\langle b | e | a \rangle$

^aFor $\omega_P - \omega_S \approx \omega_R$ as the only frequency combination resonant with a molecular transition, Raman resonant terms dominate the nonlinear response and its change across the resonance defines the spectral shape. Additional one-photon resonance is possible through the denominators such as $(\Omega_{kg} - \omega_P)$ whenever input frequencies approach electronic transitions. The spectral behaviour in this case is dominated by a few terms in the summation.

^bThe sum of all nonresonant terms constitutes a weakly dispersive background. Some terms are nonresonant for a Raman transition but can give rise to two- or three-photon absorption for a different set of input frequencies.

Let us now suppose that only two states g and f are connected through a Raman-type resonance ($\Omega_{fg} - (\omega_P - \omega_S) \simeq 0$), the rest of the denominators being well removed from zero. By inspection, it is possible to collect terms that start at either of these two levels and contribute to the spectral features of $\chi^{(3)}$. After referring all the frequencies to the lower g level, we arrive at

$$\begin{aligned} \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0\omega_P - \omega_S) &= \chi_{\mu\alpha\beta\gamma}^{(3)\text{NR}} \\ &+ \frac{N}{6\epsilon_0\hbar^3} \sum_{g,f} \frac{1}{\Omega_{fg}^* - (\omega_P - \omega_S)} \\ &\times \sum_j \left(\frac{R_g^\mu R_{ff}^\alpha}{\Omega_{fg}^* - \omega_\sigma} + \frac{R_g^\alpha R_{ff}^\mu}{\Omega_{fg}^* + \omega_0} \right) \\ &\times \sum_k \left[\rho_{gg}^{(0)} \left(\frac{R_{gk}^\beta R_{kf}^\gamma}{\Omega_{kg} - \omega_P} + \frac{R_{gk}^\gamma R_{kf}^\beta}{\Omega_{kg} + \omega_S} \right) \right. \\ &\left. - \rho_{ff}^{(0)} \left(\frac{R_{gk}^\beta R_{kf}^\gamma}{\Omega_{kg}^* - \omega_P} + \frac{R_{gk}^\gamma R_{kf}^\beta}{\Omega_{kg}^* + \omega_S} \right) \right] \end{aligned} \quad [16]$$

where N is the total number density of the chromophore. The summation in j and k runs over all molecular levels, whereas that in g, f runs over all pairs close to Raman resonance, which give rise to close-lying lines. When there is more than one chromophore, an additional summation over species should be included.

If an optical frequency ω_a is close to one-photon electronic resonance with an intermediate state j , the terms including the denominator $\Omega_{fg} - \omega_a \simeq 0$ will be dominant and we obtain a good approximation by retaining only these (resonant nonlinear Raman spectroscopy). In the absence of such additional electronic resonances, we can neglect the damping coefficient for all denominators whose absolute value is far from zero and write them in terms of real Raman scattering tensor components for the transition from g to f excited by the laser at frequency

$$\omega - (\alpha_{\delta\epsilon}(\omega))_{gf} = \frac{1}{\hbar} \sum_j \left(\frac{R_g^\epsilon R_{ff}^\delta}{\omega_{jg} - \omega} + \frac{R_g^\delta R_{ff}^\epsilon}{\omega_{jf} + \omega} \right)$$

We can further simplify by ignoring the weak dispersion of $(\alpha_{\delta\epsilon}(\omega))_{gf}$ and dropping the gf subscript. The final expression is shown in **Table 1**. We see that, in the presence of resonances, the third-order susceptibility is generally complex:

$$\chi^{(3)} = \chi^{(3)\text{NR}} + \chi'^{(3)\text{R}} + i\chi''^{(3)\text{R}} \quad [17]$$

The nonresonant part $\chi^{(3)\text{NR}}$ is real and includes the contribution of every species present. It will usually show a weak dispersion, being approximately constant for extended frequency ranges. In this case, the permutation of the frequency arguments alone does not alter much the numerical value of the susceptibility. This is the *Kleinman's symmetry conjecture* which, combined with the strict intrinsic permutation symmetry allows to freely permute

the Cartesian subscripts in $\chi^{(3)\text{NR}}$. This property, although not exact, is of great relevance for the polarization nonlinear Raman techniques.

$\chi^{(3)\text{R}}$ has both real and imaginary parts, and is additive if different transitions from the same or other chromophore overlap. Disregarding multiplicative factors, the dispersion of $\chi^{(3)\text{R}}$ has the form

$$\begin{aligned}\chi'^{(3)\text{R}} &\sim \sum_{g,f} \alpha^2 (\rho_{gg}^{(0)} - \rho_{ff}^{(0)}) \frac{\Delta_{fg}}{\Delta_{fg}^2 + \Gamma_{fg}^2} \\ \chi''^{(3)\text{R}} &\sim \pm \sum_{g,f} \alpha^2 (\rho_{gg}^{(0)} - \rho_{ff}^{(0)}) \frac{\Delta_{fg}}{\Delta_{fg}^2 + \Gamma_{fg}^2}\end{aligned}\quad [18]$$

The imaginary part has a Lorentzian profile of half-width Γ_{fg} centred at exact resonance. This Lorentzian line shape comes from the assumed form for the damping terms, and more realistic models should be used in eqn [14] when studying line shapes. The spectral shape is the same as for spontaneous Raman lines. The real part of $\chi^{(3)\text{R}}$ is multiplied by the detuning and shows a dispersive line shape. $\chi^{(3)\text{R}}$ depends on the population difference, instead of just the population of the initial state as does spontaneous Raman. This dependence can lead to saturation whenever appreciable population is transferred to the excited level.

Generation, Evolution and Detection of the Signal Field

The last step is to analyse how the induced nonlinear polarization creates a new wave or interferes with the existing ones to generate the nonlinear Raman signal. The nonlinear wave propagation equation (taking $\mathbf{P}^{(2)} = 0$) is

$$\nabla \times \nabla \times \mathbf{E}(\omega) = \frac{\omega^2}{c^2} \varepsilon(\omega) \mathbf{E}(\omega) + \omega^2 \mu_0 \mathbf{P}^{(3)}(\omega) \quad [19]$$

where $\varepsilon(\omega) = \mathbf{1} + \chi^{(1)}(-\omega; \omega)$ is the dielectric tensor that accounts for the linear propagation. We look for solutions in the form of running plane waves propagating collinearly along the z axis, orthogonal to the electric field vector, and suppose that the amplitude of the signal field will change slowly along z . We will restrict ourselves to the small-gain regime, in which neither appreciable depletion of the input beams nor population transfer occurs, leading to an amplitude rate change given by

$$\begin{aligned}\frac{\partial E_{\omega\sigma\mu}(z)}{\partial z} &= \frac{i\omega_\sigma}{2c n_\sigma} \left(\frac{D}{4} \right) \chi_{\mu\alpha\beta\gamma}^{(3)}(-\omega_\sigma; \omega_0\omega_p - \omega_s) \\ &\quad \times E_{\omega_0\alpha}(z) E_{\omega_p\beta}(z) E_{\omega_s\gamma}^*(z) \exp(i\Delta k z)\end{aligned}\quad [20]$$

where $\Delta k = (k_0 + k_p - k_s) - k_\sigma$ is the phase mismatch, i.e. the difference between the wave vector of the 'polarization wave' at frequency ω_σ and that of the signal field at the same frequency. The former value is a combination

of the refractive index at the input frequencies, whereas the latter depends on the refractive index at ω_σ . Owing to linear dispersion, these two values are in principle different. If $\Delta k \neq 0$, the change rate of the signal amplitude shows an oscillatory behaviour, whereas for $\Delta k = 0$ (perfect phase match) a monotonic change is obtained (increase or decrease depending upon the argument of the complex susceptibility) leading to a higher signal. In the small-signal regime we can integrate eqn [20] and evaluate the intensity at the detector, given by $I_{\omega_j} = \frac{1}{2} \varepsilon_0 c n_j |E_j|^2$.

We are at last able to give a plane wave signal expression for the different nonlinear Raman techniques, collected in **Table 1**.

In several techniques we monitor the intensity at a new frequency (normal CARS, Raman resonant four-wave mixing), a new polarization (RIKES) or both (polarization CARS). The generated wave does not interfere with the input waves and the output intensity depends on the product of three input intensities, the square of the interaction length, within the coherence length of lasers, and the square of the effective susceptibility. If $\omega_\sigma = \omega_p$ or ω_s , the phase matching is automatic; in other cases it must be set by controlling the refraction index or crossing the beams.

The quadratic dependence with $\chi^{(3)}$ leads to interference among neighbouring lines, from the same or different species, and with the nonresonant background in dense media, which can lead to strongly distorted line-shapes. The different tensorial properties of $\chi^{(3)\text{R}}$ and $\chi^{(3)\text{NR}}$ can be exploited to reduce background interference, by using input waves with circular polarization or linear along a direction chosen to cancel the non-resonant part.

In other techniques, we monitor the change in intensity for the pump or Stokes beam. We can solve eqn [20] considering the input field as variable, leading to an exponential amplitude change that can be approximated by a linear change in the small signal regime, or keeping it constant as before. For the latter method we must include the interference of signal and input fields at the detector, which shows a close connection with heterodyne detection techniques. Both methods lead to the same result in the small-gain regime, showing a decrease in the pump intensity (SRL) and an increase in the Stokes intensity (SRG), linear with the imaginary resonant part of the susceptibility $\chi'^{(3)\text{R}}$, i.e. proportional to the spontaneous Raman spectrum and free from interference effects, automatically phase-matched and dependent on the product of pump and Stokes intensities.

The signal expressions in **Table 1** allow for an analysis of the spectral properties of the relevant techniques. In actual experiments, beams are focused and the detailed geometry must be considered.

γ	magnetogyric ratio
η	NOE
ρ	self-relaxation rate
σ_{IS}	mutual cross-relaxation rate
τ_c	correlation time
τ_m	mixing time
ω	Larmor frequency

Introduction

The nuclear Overhauser effect (NOE) has become one of the key effects for obtaining the structures of molecules, especially biomolecules, in solution by nuclear magnetic resonance (NMR) spectroscopy. The effect was first enunciated by its discoverer, Overhauser, as a large polarization of nuclear spins in metals on saturation of electrons to which they are coupled. Neither its discoverer, nor the famous people in the audience at the conference where he first presented his calculation in 1953, nor Charles Slichter, who took upon himself the task of experimentally verifying Overhauser's assertions, could have imagined that the effect would become the backbone of modern NMR. The effect remained as a curiosity and was sparingly used until its transformation into the nuclear–nuclear Overhauser effect, in which one of the nuclear spins is saturated and the nearby nuclear spin shows changes in the intensity of its NMR signal. For small molecules, in the fast motion limit, the Overhauser effect is positive for nuclear spins with the same sign of γ (the magnetogyric ratio) and negative for those with opposite sign.

The nuclear–nuclear Overhauser effect, in its early days, was used for enhancing the polarization of less-sensitive nuclei, such as natural abundant ^{13}C or ^{15}N and in double-resonance experiments for obtaining additional information on relaxation of molecules. It was utilized, in conjunction with the spin–lattice relaxation of various carbons, for the characterization of anisotropy of molecular reorientations.

However, its largest utility continued to be for obtaining information on molecular conformations, by selectively saturating the magnetization of a specific proton in the molecule and monitoring the changes in the intensity of resonances of nearby protons.

In continuous wave (CW) NMR, one of the problems is the separation of the Overhauser effect from the coherent effects of radiofrequency (RF) irradiation. For example, even at very low RF field (~ 0.02 Hz) CW double resonance experiments, the observed intensities can only be explained by including coherent effects, as splitting or broadening of directly connected transitions. In higher power experiments, the lines are split and several coherent effects are simultaneously present. The development of one-dimensional (1D) Fourier transform NMR immediately freed the nuclear Overhauser effect from the shackles of such coherent effects. The irradiation can be time-shared, such that the saturating RF field is applied before the observation pulse. Since, during observation, the RF field and hence the coherent effects are absent, the spectrum contains information only on relaxation. The development of 1D Fourier transform NMR, with its added sensitivity advantage, opened the field of NMR, to the study of proton NMR of biomolecules. As soon as such spectra were recorded, the assignment of the large number of resonances became a major problem. Selective decoupling and NOEs were employed, respectively, to assign and to obtain information on the secondary structures of peptides and proteins. In small peptides, it became a matter of routine to pick up a few characteristic NOEs and assign the secondary structure. For larger peptides, containing 20–50 amino acid residues, efforts were directed towards obtaining a large number of (50–100) selective decoupling and NOE experiments, to assign the spectra and to obtain the three-dimensional (3D) structure of the molecules. However, it was hard work to manually plot, measure and analyse these large number of 1D spectra. The development of two-dimensional (2D) NMR removed this obstacle. COSY NMR spectroscopy with its many improvements is used for identifying coherently coupled spins, while the 2D NOESY experiment is used for obtaining large-scale information on distances between nearby spins. The success of this algorithm prompted workers to look at even larger molecules (of relative molecular mass 10–15 kDa), crowding even the

2D spectra, and necessitating addition of a third or even fourth dimension to remove overlap. This was achieved by labelling the biomolecules with either ^{13}C and/or ^{15}N and spreading the 2D information into a third or fourth dimension, as a function of attached carbon or nitrogen chemical shifts. Selective polarization transfers (from a selected heteronucleus to a selected proton) followed by NOE are being developed to enhance the resolution and to reduce the burden of 2D or 3D NMR experiments.

Theory

In the NOE, the non-equilibrium magnetization of a spin is shared by nearby spins through mutual dipole–dipole relaxation. Any other relaxation mechanism, if present, attenuates the effect. For example, dissolved paramagnetic oxygen has a deleterious effect on the NOE. It is therefore necessary to have clean solvents and often it becomes necessary to remove the dissolved oxygen for a quantitative estimate of NOEs.

The source spin is brought to a non-equilibrium state, for example by selectively saturating its magnetization by a low power, long pulse. During this irradiation, the transfer of magnetization to the other nearby spins also takes place and this can be monitored as a function of the irradiation time. The irradiation can be performed for a sufficiently long time, so that a steady state is reached between the irradiation and the relaxation and this gives rise to what is known as ‘steady state NOE’. However, such experiments, particularly in case of slowly re-orienting molecules, give NOEs between fairly distant spins in the molecule, through migration of magnetization over several intervening spins (the phenomenon is known as ‘spin-diffusion’). This has the disadvantage that the NOE loses selectivity of information. A simple alternative is to reduce the irradiation time or to monitor the growth of the NOE, as a function of irradiation time. This has been called ‘truncated-driven-NOE’. In both these experiments, the NOE transfer takes place in the presence of the RF field. In another experiment, the source spin is selectively inverted (by a selective π pulse) and the NOE is monitored in the absence of the RF field. This is known as ‘transient-NOE’, and was first suggested by Solomon.

The 2D NOE (NOESY) experiment is formally equivalent to a large number of transient NOE experiments. Each cross-section of a 2D NOESY spectrum is equivalent to a 1D selective transient NOE experiment, in which the peak corresponding to the diagonal is selectively inverted. The NOE transfer in both NOESY and 1D transient NOE takes place in the absence of the RF field and, theoretically, the two experiments are identical (except for a factor of 2 in the intensities of 1D experiments which will be explained later). The theory of the NOE,

given in the following subsections, is divided into three parts: (i) steady-state NOE, (ii) transient NOE and (iii) 2D NOE (NOESY). Later sections describe the NOE in the rotating frame, heteronuclear NOE and transferred NOE.

In this article the NOE between various spins will be discussed, ignoring the spin–spin coupling between various spins and the associated splitting of lines into multiplet components. A spin will be assumed to be irradiated (saturated or inverted) as a whole and detected as a whole. This description leaves out many interesting effects, such as selective saturation of various transitions, direct pumping effects of irradiation or inversion, multiplet effects between various transitions of a spin arising from cross-correlations and strong coupling effects.

Steady-State NOE

Consider a two-spin- $\frac{1}{2}$ system, with spins I and S relaxation coupled to each other. Relaxation of these two spins in the presence of mutual cross-relaxation is described by coupled rate equations known as Solomon’s equations:

$$\frac{dI_z(t)}{dt} = -\rho_I(I_z(t) - I_z^{\text{eq}}) - \sigma_{IS}(S_z(t) - S_z^{\text{eq}}) \quad [1]$$

$$\frac{dS_z(t)}{dt} = -\sigma_{SI}(I_z(t) - I_z^{\text{eq}}) - \rho_S(S_z(t) - S_z^{\text{eq}}) \quad [2]$$

where $I_z(t)$ and $S_z(t)$ describe the instantaneous values of the longitudinal magnetization of the spins I and S and I_z^{eq} and S_z^{eq} represent their equilibrium values respectively. The terms ρ_I and ρ_S are the self-relaxation rates of the two spins, respectively, and $\sigma_{IS} = \sigma_{SI}$ is the mutual cross-relaxation (NOE) rate between the spins. All these rates depend on the mechanics of relaxation operative in the spin system and the state of mobility of the molecule in which they are embedded.

On selective saturation by RF irradiation at the resonance frequency of one of the spins (say S), it is generally assumed that the magnetization of the irradiated spin is fully saturated at all times, that is $S_z(t) = 0$, for all values of t . The steady-state solution of the Solomon’s equations is then obtained by making the time derivatives on the left-hand side of eqns [1] and [2] as equal to zero, yielding the steady-state value of I_z from eqn [1] as

$$I_z^{\text{ss}} - I_z^{\text{eq}} = \frac{\sigma_{IS}}{\rho_I} S_z^{\text{eq}} \quad [3]$$

Since $I_z^{\text{eq}}/S_z^{\text{eq}} = \gamma_I/\gamma_S$, one obtains the well-known steady-state NOE as

$$\eta = \frac{I_z^{\text{ss}} - I_z^{\text{eq}}}{I_z^{\text{eq}}} = \frac{\gamma_S}{\gamma_I} \frac{\sigma_{IS}}{\rho_I} \quad [4]$$

For two relaxation coupled spins, each spin- $\frac{1}{2}$, the energy level diagram consists of four levels (**Figure 1**).

From this diagram it is seen that W_{1I} and W_{1S} are the single-quantum transition probabilities for the spin I and S

Figure 1 Energy-level diagram of a two-spin- $\frac{1}{2}$ system, showing the transition probabilities and the spin states. The designation $\alpha\alpha$ means both the spins are in the $+\frac{1}{2}$ state, while $\alpha\beta$ means the first spin (I) is in the $+\frac{1}{2}$ state and the second spin (S) is in $-\frac{1}{2}$ state. W_{1I} gives the single-quantum transition probability for the I spin when it changes its spin state. W_0 and W_2 are the zero- and double-quantum transition probabilities, respectively, by which both the I and S spins simultaneously change their spin states.

respectively. The term W_{0IS} is the zero-quantum transition probability for the flip-flop process, in which the two spins are in opposite spin states and exchange their spin states; W_{2IS} is the double-quantum transition probability, by which the two spins in the similar states simultaneously change their spin states. In homonuclear systems, these probabilities are proportional to the spectral densities at 0, ω and 2ω frequencies, respectively, for W_0 , W_1 and W_2 , where ω is the Larmor frequency. Using population rate equations of the four levels of the two-spin system and using these transition probabilities connecting the four levels, it is straightforward to show that

$$\begin{aligned}\sigma_{IS} &= W_{2IS} - W_{0IS} \\ \rho_I &= W_{0IS} + 2W_{1I} + W_{2IS} \\ \rho_S &= W_{0IS} + 2W_{1S} + W_{2IS}\end{aligned}\quad [5]$$

Using eqn [5] in eqn [4] the NOE on spin I , on saturating spin S , is obtained as

$$\eta\{S\} = \left(\frac{\gamma_S}{\gamma_I}\right) \frac{W_{2IS} - W_{0IS}}{W_{0IS} + 2W_{1I} + W_{2IS}} \quad [6]$$

The origin of the NOE can now be explained in the following way. After the selected spins absorb a certain amount of energy from the RF field, they pass this energy to the other spins and to other degrees of freedom, known as the lattice. In other words, they start to relax. Mutual dipolar interaction between the nearby spins

provides an effective mechanism for exchange of energy among the spins and to the lattice. However, if these spins are embedded in a rigid solid, the dipolar interaction is time independent and does not couple the spins to the lattice. Except in the case of like spins (same γ), the dipolar interaction in rigid solids does provide a mechanism of rapidly passing the energy from one spin to the next (via its energy conserving flip-flop, W_0 , terms). This process, known as spin diffusion in solids, is responsible for migration of magnetization across the whole sample and to relaxation sinks such as rapidly rotating methyl groups or rapidly relaxing paramagnetic centres. On the other hand, if the interacting spins are on molecules in solution, which are rapidly reorienting, the dipolar interaction becomes time dependent and, if there are molecular motions at the Larmor or twice the Larmor frequency, it couples the spins to the rotational degrees of freedom of the molecule and transfers the spin energy to the lattice. The lattice is assumed to have infinite heat capacity and remains at thermal equilibrium at room or sample temperature. The coupling of the spin to the lattice at the Larmor frequency is provided additionally by several other mechanisms, such as modulation of chemical shift anisotropy, quadrupolar interaction and paramagnetic relaxation centres. All these contribute to W_1 but not to W_0 and W_2 , and attenuate the NOE, as seen from eqn [6]. It is only the dipolar interaction that has two spin terms, such as I_+S_- , I_-S_+ and I_+S_+ , I_-S_- , which contribute, respectively, to W_0 and W_2 and in turn to the NOE. The first two are flip-flop terms or zero-quantum terms, in which the two spins exchange energy between each other without requiring exchange of energy with the lattice (for $\gamma_I = \gamma_S$). Such processes dominate for slowly reorienting molecules such as biomolecules; and therefore the NOE is very significant in such cases, as hardly any energy is lost to the lattice. Here W_0 dominates over all the other terms, and as seen from eqn [6], the NOE is large and negative (-1). The third and the fourth terms, I_+S_+ and I_-S_- are the two quantum terms and the exchange energy of the spins with the lattice at twice the Larmor frequency. In this case, both the spins flip simultaneously either up or down. If molecular motions are fast enough to have spectral densities at 2ω , then these processes dominate. It can be shown that in such circumstances the NOE is positive and small, with a maximum of $+0.5$.

The spectral densities for the various motional regimes are schematically sketched in Figure 2.

In the slow motion or long correlation time limit ($\tau_c \gg 1/\omega_0$), the spectral densities are maximum near the zero frequency and minimum at ω_0 and $2\omega_0$, while for fast reorienting molecules $\tau_c \ll 1/\omega_0$ the spectral density is almost equal for all the frequencies till $\omega_c = 1/\tau_c$, where τ_c is the correlation time for molecular reorientations. For the dipolar interaction between spins I and S ,

Figure 2 Spectral density $J(\omega)$ for three values of correlation time, plotted as a function of frequency ω . The spectral density has a cutoff frequency $\omega_c = 1/\tau_c$, where τ_c is the correlation time of molecular reorientations. As molecular reorientations become faster, τ_c decreases and the spectral density dispersion becomes flatter. The terms T_1 , T_2 and NOE depend on the value of the spectral densities at 0 , ω_0 and $2\omega_0$, where ω_0 is the Larmor frequency. (a) Spectral density for slowly reorienting molecules which have long correlation times ($\tau_c \gg 1/\omega_0$). In such cases the spectral density has a negligible value at ω_0 and $2\omega_0$, but large values at low frequencies. (b) Spectral density for intermediate values of correlation times, for which $\tau_c \approx 1/\omega_0$. (c) Spectral density for small molecules undergoing fast reorientation, which have short correlation times ($\tau_c \ll 1/\omega_0$) and the spectral density has nearly equal values from 0 to $2\omega_0$. Since the area under the curves is constant, the spectral density has different magnitudes at each frequency in the above three cases.

the transition probabilities for isotropic molecular reorientations are obtained as

$$\begin{aligned} W_{0IS} &= \frac{1}{10} k^2 \frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} \\ W_{1I} &= \frac{3}{20} k^2 \frac{\tau_c}{1 + \omega_I^2 \tau_c^2} \\ W_{1S} &= \frac{3}{20} k^2 \frac{\tau_c}{1 + \omega_S^2 \tau_c^2} \\ W_{2IS} &= \frac{6}{10} k^2 \frac{\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \end{aligned} \quad [7]$$

where $k = (\mu_0/4\pi)\gamma_A\gamma_X\hbar r_{IS}^{-3}$.

Homonuclear case

When the two spins are of the same species, i.e. $\gamma_I = \gamma_S$, then the steady-state homonuclear NOE for selective saturation of one of the spins with the other spin having a well-resolved chemical shift is obtained by substituting in eqn [6] $\omega_I = \omega_S = \omega$,

$$\eta_{\max} = \frac{5 + \omega^2 \tau_c^2 - 4\omega^4 \tau_c^4}{10 + 23\omega^2 \tau_c^2 + 4\omega^4 \tau_c^4} \quad [8]$$

This curve is plotted in **Figure 3**, and has the value $+0.5$ for fast reorientation with respect to ω (short correlation limit $\omega\tau_c \ll 1$) and -1 for slow reorientations (long correlation limit, $\omega\tau_c \gg 1$).

These can also be seen for homonuclear spins, by direct substitution of W_s in the two limits in eqn [6]. For example, for the short correlation time limit, $W_0 : W_1 : W_2 ::$

Figure 3 Variation of homonuclear NOE enhancement, eqn [8], plotted as a function of $\omega\tau_c$. Note the logarithmic scale of $\omega\tau_c$. For small molecules with short τ_c , the limiting value for $\eta_{\max}$ is $+0.5$. In practice, since relaxation mechanisms other than dipolar are also efficient in this extreme narrowing limit, positive enhancements as large as this are rarely observed. For large molecules with long τ_c , the limiting value of $\eta_{\max}$ is -1 . Biomolecules and small molecules in viscous solvents come into this category and generally give significant NOEs. In the central region where $\eta_{\max}$ varies rapidly with $\omega\tau_c$, the NOE enhancements depend on the spectrometer frequency and the molecular tumbling rate. The value of $\eta_{\max}$ passes through a null for $\omega\tau_c \approx 1$.

$2 : 3 : 12$, yielding $\eta = \frac{1}{2}$. For the long correlation time limit, W_1 and W_2 are negligible and $\eta = -1$. From eqn [8] and from **Figure 3** it is seen that $\eta = 0$, for $\omega\tau_c = 1.118$. This is often called the critical correlation time limit. In this limit, $W_0 = W_2$, $\sigma = 0$ and the laboratory frame NOE is zero. Experiments have been designed in which both the spins are spin-locked along an axis making an angle θ from the z -direction, yielding a non-zero NOE. This will be described in the section on 'rotating-frame NOE'. The short correlation time limit, $\omega\tau_c \ll 1$ is generally applicable to small molecules (relative molecular mass ≤ 1 kDa) at low spectrometer frequencies, as was often the case in the early days of NMR. For larger size molecules, which reorient slowly ($\omega\tau_c \gg 1$) the NOE is negative, but very useful in obtaining information on the proximity of the spins.

The observation of negative NOE among the spins with the same sign of γ and in the short correlation time limit, however, gave rise to some excitement during the late 1960s. It was soon found that the negative NOE arose from what was called a 'three-spin effect'. The explanation is as follows. When the first spin is saturated, the second spin is enhanced in intensity. By logical extension this means that the third spin is reduced in intensity. This of course requires that the three spins are in almost a linear configuration, such that the direct positive NOE from the first spin to the third is less than the transmitted NOE via the second spin. The observation of the negative three-spin effect for homonuclear spins in the short

correlation time limit is thus a signature of the linearity or near-linearity of the three spins. The other observation of a negative NOE between two protons, without the intervention of a third spin in a polypeptide by Balaram and co-workers, was the first evidence of molecules tumbling at rates slower than the Larmor frequency. Ever since then, larger molecules have been studied by NMR spectrometers operating at higher frequencies, and negative NOEs between protons have become the backbone of NMR research. There is an additional advantage of negative NOEs, which becomes apparent in the transient NOE experiment, described in the next section.

Transient NOE

In the transient NOE experiment, the perturbed spin is selectively inverted rather than saturated. Since this can be done in times short compared with T_1 and T_2 of the spins, the NOE during the pulse is neglected and the migration of the magnetization is observed after the pulse, in the absence of the RF field. The time evolution of magnetization is obtained using Solomon's eqns [1] and [2]. Substituting the initial condition, $S_z(0) = -S_z^{\text{eq}}$, one obtains a biexponential time evolution for I_z and S_z magnetization, assuming $\rho_I = \rho_S = \rho_{IS}$, as

$$\frac{S_z(t) - S_z^{\text{eq}}}{S_z^{\text{eq}}} = -e^{-(\rho_{IS} + \sigma_{IS})t} - e^{-(\rho_{IS} - \sigma_{IS})t} \quad [9]$$

$$\frac{I_z(t) - I_z^{\text{eq}}}{I_z^{\text{eq}}} = -e^{-(\rho_{IS} + \sigma_{IS})t} + e^{-(\rho_{IS} - \sigma_{IS})t} \quad [10]$$

While the recovery of the inverted spin S_z to its equilibrium value is biexponential, that of I_z magnetization shows an initial growth and then a decay. Equation [10] can be rewritten as

$$\frac{I_z(t) - I_z^{\text{eq}}}{I_z^{\text{eq}}} = [1 - e^{-2\sigma_{IS}t}]e^{-(\rho_{IS} - \sigma_{IS})t} \quad [11]$$

This gives the NOE on spin I , which is positive for positive γ and negative for negative. The NOE on spin I grows, reaches a maximum and then decays to zero. The initial rate of growth is obtained by differentiating eqn [11] with respect to time and taking the limit $t \rightarrow 0$, the so-called initial rate approximation, yielding

$$\frac{d}{dt} \left(\frac{I_z(t) - I_z^{\text{eq}}}{I_z^{\text{eq}}} \right)_{t \rightarrow 0} = 2\sigma_{IS} \quad [12]$$

The initial rate of growth of NOE thus gives a direct measure of the cross-relaxation rate σ_{IS} and by inference the distance r_{IS} (σ_{IS} is proportional to r_{IS}^{-6})

The advantage of the transient NOE experiment is that the transport of magnetization takes place in the absence of RF irradiation and also the dynamics of Solomon's

equations are identical to the 2D NOE experiment, described in the next section. The driven experiment has no 2D analogue and the solution given earlier in eqn [4] has the limitation that the details of saturation are not included. In fact if one uses eqn [2] instead of eqn [1], for the steady-state solution, by substituting $dS_z(t)/dt = 0$, $S_z(t) = 0$, one obtains a wrong result

$$\frac{I_z(t) - I_z^{\text{eq}}}{S_z^{\text{eq}}} = \frac{\rho_S}{\sigma_{IS}} \quad [13]$$

Boulat and Bodenhausen earlier and more recently Karthik have shown how this anomaly can be removed by describing the details of the saturation process of spin S .

Two-Dimensional NOE (NOESY)

Selective saturation or inversion of each transition out of a large number of closely spaced transitions of various protons of a protein is both tedious and difficult. The development of the 2D NOE or NOESY experiment was

Figure 4 (a) The 2D NOESY pulse sequence, which uses three 90° pulses. The times t_1 and t_2 are the evolution and detection periods, respectively; τ_m is the mixing time during which only longitudinal magnetization is retained, either by gradients or by cycling the phases (ϕ_1, ϕ_2, ϕ_3) of the pulses. (b) Schematic NOESY spectrum, showing that in such spectra the NOEs are manifested as cross-peaks between the various spins, the resonances of which lie on the diagonal.

therefore a turning point in the application of NMR for the study of biomolecules. The 2D NOE experiment, **Figure 4(a)**, uses three 90° pulses. The first pulse flips the magnetization of all the spins in the molecule to the transverse plane, which are then allowed to evolve during a frequency labelling period t_1 . The second pulse flips the magnetization to the longitudinal direction. This non-equilibrium magnetization is allowed to relax and gives NOEs according to eqns [1] and [2] during the mixing period τ_m . The state of the spin system is read by the third 90° pulse with the signal being recorded as a function of the time variable t_2 . A complete set of data $s(t_1, t_2)$ after Fourier transformation with respect to both t_1 and t_2 yields a 2D spectrum (**Figure 4(b)**).

The magnetization components, which have the same frequencies in time domains t_1 and t_2 , lie along the diagonal of the NOESY spectrum, while those magnetization components which have crossed over from one spin to another spin during the mixing time τ_m , owing to the NOE, lie on both sides of the diagonal and are called the cross-peaks. Indeed, it has been shown that a cross-section parallel to ω_2 is identical, except for a factor of 2, to a 1D transient difference NOE experiment in which the peak on the diagonal is selectively inverted. Suppression of

transverse magnetization during τ_m and the growth of longitudinal magnetization during τ_m (giving rise to an axial peak in the 2D spectrum) can be achieved either by phase cycling or by the use of gradients. The factor of 2 difference arises between the 1D and 2D experiment owing to the fact that the axial magnetization does not contribute in the 2D, but it does in the 1D experiment. However, the rate of transfer and hence the information content is identical in the two experiments. The first 2D NOE spectrum of a small protein, basic pancreatic trypsin inhibitor (BPTI) is shown in **Figure 5**.

A large number of cross-peaks are observed, each indicating a NOE or exchange between the protons of the corresponding diagonals. Exchange also gives rise to cross-peaks identical to the negative NOE (same sign as the diagonal) and can only be distinguished from NOE by the use of the rotating frame NOE method, to be discussed later. The data in the NOESY experiment are analysed by measuring the peak volume of a cross-peak in a series of 2D experiments with various mixing times τ_m . The initial rate of growth of the NOE is directly proportional to $1/r^6$. To obtain the proportionality constant, the rate is compared with some known distance. However, this procedure is strictly valid for only two relaxation coupled spins. Since

Figure 5 Contour plot of the ^1H NOESY spectrum at 360 MHz of the basic pancreatic trypsin inhibitor. The protein concentration was 0.02 M, solvent D_2O , $\text{pD} = 3.8$, $T = 18^\circ\text{C}$. The spectral width was 4000 Hz; 512 data points were used in each dimension; 56 transients were accumulated for each value of t_1 . The mixing time τ_m was 100 ms. The absolute value spectrum, obtained after digital filtering in both dimensions with a shifted sine bell, is shown. NOE connectivities for selected amino acid residues are indicated by the broken lines. Reproduced with permission of Academic Press from Kumar A, Ernst RR, and Wüthrich K (1980) *Biochemistry and Biophysics Research Communications* 95: 1.

there are, in general, several spins simultaneously coupled by relaxation to each other, the two-spin problem is generalized in the following manner.

Generalized Solomon's Equations

If there are more than two spins, relaxation coupled to each other, then the two-spin Solomon's eqns [1] and [2] can be generalized in the following manner

$$\frac{d(I_{zi}(t) - I_{zi}^{\text{eq}})}{dt} = -\rho_i(I_{zi} - I_{zi}^{\text{eq}}) - \sum_{j \neq i} \sigma_{ij}(I_{zj} - I_{zj}^{\text{eq}}) \quad [14]$$

which states that there are n ($i = 1 \dots n$) coupled equations describing the self-relaxation of each spin via the term ρ_i and the cross-relaxation with the other spins via σ_{ij} . This is a straightforward extension of the pairwise interaction, and it neglects any cross-terms (cross-correlations) that may be present between the relaxation of various spins. It has been shown that the effect of cross-correlations on the total NOE (the average NOE, neglecting differences in the intensities of various transitions of a spin) is generally small. In this article, the effect of cross-correlation on NOE will not be dealt with and the reader is referred to several articles on this field, including a review by the authors. The general solution of eqn [14] is a multiexponential time evolution of magnetizations which are coupled to each other. Once the geometry of the spins is known, it is possible to calculate the various rates of eqn [14] and compute the expected auto- and cross-peak intensities of the NOESY experiment. These computed intensities are then iteratively fitted to the observed intensities, to converge on possible structure(s) consistent with the observed intensities. Often there are differences between the computed intensities and the observed intensities that arise from internal motions, which in turn when built into the calculations give information on the internal motions. Anisotropy of reorientation of the molecules also plays a role and can also be built into the NOE calculations.

Three-dimensional structures of a large number of biomolecules (proteins, peptides, oligonucleotides and oligosaccharides) have been obtained using information derived from the NOESY experiments. The reader is referred to the 1986 book by Wüthrich and the *Encyclopedia of Nuclear Magnetic Resonance* for an exhaustive review up to 1996.

Two-dimensional NOE (ROESY)

For intermediate-size molecules for which $\omega\tau_c \approx 1$, the zero-quantum (W_{0IS}) and double-quantum (W_{2IS}) transition probabilities are nearly equal and the cross-relaxation rate σ_{IS} approaches zero. In such cases there is no NOE. Bothner-By came up with the fascinating idea of

Figure 6 Rotating frame NOE pulse sequences. The 1D experiment requires two sequences, represented by (a) and (b). (a) is the reference experiment in which a 90°_x non-selective pulse is applied on all the spins, followed by a spin-lock along the y-direction for a time τ_m and the state of the spin system is detected. (b) The control experiment in which a selective 180° pulse inverts the magnetization of the spin from which the NOE is to be observed before the 90°_x pulse and the experiment is continued as (a). The 1D NOE spectrum is the difference between the spectra obtained with the sequence (a) and (b). (c) The 2D ROESY sequence. The times t_1 and t_2 are the evolution and detection periods and τ_m is the mixing time. SL refers to the low-power spin-locking RF field.

doing cross-relaxation in the transverse plane by spin-locking the magnetization, using RF fields. He named the technique as CAMELSPIN (cross-relaxation appropriate for minimolecules emulated by locked spins), but it is now known as ROESY (rotating frame NOESY). Both 1D and 2D versions are known, and are shown schematically in Figure 6. The method will be explained using the 1D experiment; the 2D logic is identical. The first 90° pulse (Figure 6(a)) flips the magnetization to the transverse plane, followed by a spin-lock using a 90° phase-shift.

The spin-locked magnetization of the two spins, which differ in chemical shifts, decay and cross-relax according to the rate equations,

$$\begin{aligned} \frac{dm_I(t)}{dt} &= \rho_I m_I(t) - \sigma_{IS} m_S(t) \\ \frac{dm_S(t)}{dt} &= \sigma_{SI} m_S(t) - \rho_S m_S(t) \end{aligned} \quad [15]$$

where m_I and m_S are the transverse magnetization of spins I and S spin-locked along the RF field. For the 1D case, two experiments (reference and control) are performed. For the reference experiment (Figure 6(a)), the initial condition is $m_I(0) = m_S(0) = 1$, while for the control

experiment (Figure 6(b)), in which the magnetization of spin S is selectively inverted just before nonselective spin-lock, the initial condition is $m_I(0) = 1$, $m_S(0) = -1$. The solution of eqn [15] for these two cases can be written, respectively (for $\rho_I = \rho_S = \rho$ and $\sigma_{IS} = \sigma_{SI} = \sigma$), as

$$\begin{aligned} m_I^r(t) &= e^{-(\rho+\sigma)t} \\ m_I^c(t) &= e^{-(\rho-\sigma)t} \end{aligned} \quad [16]$$

The NOE is the difference of the two experiments and is therefore given by

$$\eta = e^{-(\rho-\sigma)t} - e^{-(\rho+\sigma)t} \quad [17]$$

$\eta_{\max}$ is obtained as

$$\begin{aligned} \eta_{\max} &= \left(\frac{\rho+\sigma}{\rho-\sigma} \right)^{-\frac{(\rho-\sigma)}{2\sigma}} - \left(\frac{\rho+\sigma}{\rho-\sigma} \right)^{-\frac{(\rho+\sigma)}{2\sigma}} \\ t_{\max} &= \frac{1}{2\sigma} \ln \left(\frac{\rho+\sigma}{\rho-\sigma} \right) \end{aligned} \quad [18]$$

ρ and σ in the above equations for homonuclear spins are obtained as

$$\begin{aligned} \rho &= \frac{3}{4} \gamma^4 \hbar^2 \left[\frac{3}{8} J(0) + \frac{15}{4} J(\omega) + \frac{3}{8} J(2\omega) \right] \\ \sigma &= \frac{3}{4} \gamma^4 \hbar^2 \left[\frac{1}{6} J(0) + \frac{3}{2} J(\omega) \right] \end{aligned} \quad [19]$$

For isotropic Brownian motion, the spectral densities are obtained as

$$\begin{aligned} J(0) &= \frac{1}{r^6} \frac{24}{15} \tau_c, \\ J(\omega) &= \frac{1}{r^6} \frac{4}{15} \left(\frac{\tau_c}{1 + \omega^2 \tau_c^2} \right) \\ J(2\omega) &= \frac{1}{r^6} \frac{16}{15} \left(\frac{\tau_c}{1 + 4\omega^2 \tau_c^2} \right) \end{aligned} \quad [20]$$

Using these values for the spectral densities, the expressions for ρ and σ in eqn [19] reduce to

$$\begin{aligned} \rho &= \frac{1}{20} \left(\frac{\gamma^4 \hbar^2}{r^6} \right) \left\{ 5\tau_c + \frac{9\tau_c}{1 + \omega^2 \tau_c^2} + \frac{6\tau_c}{1 + 4\omega^2 \tau_c^2} \right\} \\ \sigma &= \frac{1}{20} \left(\frac{\gamma^4 \hbar^2}{r^6} \right) \left\{ 4\tau_c + \frac{6\tau_c}{1 + \omega^2 \tau_c^2} \right\} \end{aligned} \quad [21]$$

The maximum NOE for these conditions is plotted in Figure 7, which has a maximum value of 38.5% for $\omega\tau_c \ll 1$ and 67.5% for $\omega\tau_c \gg 1$.

The NOE is positive and does not have a null for any correlation time. This result holds for the 2D experiment as well, with the diagonal and the cross-peaks having

Figure 7 Plot of maximum rotating frame NOE (from eqn [18]) for a homonuclear two spin- $\frac{1}{2}$ system as a function of $\omega\tau_c$. The rotating frame NOE is positive for all values of correlation time.

Figure 8 Contour plot of the 2-D ^1H ROESY spectrum of a 0.5 M solution of Boc-Val-Ala-Phe-Aib-Val-Ala-Phe-Aib-OMe in CDCl_3 , recorded at 400 MHz. A 2.25 kHz spin-lock field has been used during the 300 ms mixing period. Sixty-four scans were performed for every t_1 value and $512 \times 1\text{k}$ data were acquired. Zero filling was used to give a $1\text{k} \times 1\text{k}$ size of the displayed absorptive part of the spectrum. The diagonal drawn is negative and the cross-peaks are positive. Unpublished results by Das C, Grace RCR, and Balaram P.

opposite signs (positive NOE). A typical 2D ROESY spectrum is shown in Figure 8.

ROESY has several advantages and disadvantages. The advantages are (i) the NOE is finite (nonzero) for all sizes of the molecules, (ii) a positive NOE means that there is leakage to the lattice present and hence the magnetization

Table 1 Comparison of the salient features of ROESY, TOCSY and NOESY

Feature	ROESY	TOCSY	NOESY
Net transfer	Yes	Yes	Yes
Pure absorptive	Yes	Yes (almost)	Yes
Sign with respect to the diagonal	Opposite (+ve NOE)	Same	Opposite for $\omega\tau_c \ll 1$ Same for $\omega\tau_c \gg 1$
Mixing time	Large (>100 ms)	Small (<100 ms)	<500 ms
RF field amplitude needed	Small	Large	Not applicable

does not migrate over long distances. The limited spin-diffusion helps in selecting the nearest neighbours. (iii) The three-spin effect yields a negative NOE; this can be looked at as an advantage or a disadvantage. However, the disadvantages are (i) The ROESY intensities are sensitive to the magnitude of the spin-locking RF field and to their resonance offsets. (ii) There is also a coherence transfer due to J -coupling, known as TOCSY (total correlation spectroscopy). In fact an identical pulse scheme can also be used for obtaining a TOCSY spectrum, with which one identifies all the resonances which are J -coupled through bonds. For example, all the resonances of an amino acid residue could be identified by taking a cross-section at either the NH or α H position. The salient features of ROESY, TOCSY and NOESY are listed in **Table 1**.

Some of these differences are therefore utilized for differentiating the TOCSY and ROESY peaks, in particular the strength of the spin-locking field and the mixing time, as well as the sign of the cross-peak. Experiments have also been designed for obtaining clean TOCSY as well as clean ROESY spectra.

Heteronuclear NOE

So far we have discussed the NOE between nuclei having the same γ . The maximum use of these homonuclear NOEs has been for proton–proton NOEs. However, the heteronuclear NOE also has a long history. In the early days of NMR, the heteronuclear NOE was basically utilized for the enhancement of the intensities of low γ nuclei. For example, the steady-state NOE, on spin I on irradiation of spin S when spins I and S are mutually dipolar-relaxation coupled is given by eqns [4] and [6]. For $\omega\tau_c \ll 1$, $W_0 : W_1 : W_2 :: 2 : 3 : 12$, $\sigma = \frac{1}{2}\rho$, yielding

$$\eta_I\{S\} = \frac{1}{2} \frac{\gamma_S}{\gamma_I} \quad [22]$$

Thus, for ^{13}C the NOE is 2, while for ^{15}N it is -5 . The ^{13}C magnetization could thus be enhanced by 200% by adding the NOE to carbon equilibrium magnetization. For ^{15}N , the enhancement was -4 , which is like a 400% increase in the signal. These enhancements have been and are routinely utilized in heteronuclear NMR experiments.

As $\omega\tau_c$ increases, the heteronuclear NOE decreases in magnitude (approaching zero for $\omega\tau_c \gg 1$) since in the

heteronuclear case the flip-flop process becomes non-energy conserving and requires spectral densities at a frequency equal to the difference in the Larmor frequencies of the two spins. Even the NOES for heteronuclei are very small as σ approaches zero. Therefore, heteronuclear NOE has been used only for small molecules in the $\omega\tau_c \ll 1$ limit, and there is even a 2D version known as HOESY which uses identical logic as NOESY, except that the first two pulses are applied on the source spin and the third pulse on the target spin, with the detection on the target spin.

Transferred NOE (TRNOE)

NOE measurements are also made on spin systems undergoing chemical exchange in which a small ligand molecule (peptide, drug molecule) exchanges between free and bound states with a large host molecule (protein). Under this condition, the rotational correlation time of the small molecule changes from a regime of $\omega\tau_c \ll 1$ in the free state to $\omega\tau_c \gg 1$ in the bound state. While sharp resonances of the ligand are observed only from its free state, the bulk of the NOE takes place when the ligand is in the bound state, giving rise to negative NOE between the various protons of the ligand. This is known as the transferred NOE. The observed NOE is related to the various exchange rates, concentration ratios of the two molecules and the binding constants. The transfer NOE experiment is thus often exploited for obtaining information on the exchange kinetics of ligand–protein interactions.

Conclusions

The NOE arises from mutual dipolar relaxation of nearby spins and is utilized for identifying spins which are close in proximity in reorienting molecules. The NOE thus provides information on the 3D structures of the molecules in solution and has led to an alternate methodology of obtaining structure of biomolecules in solution as compared with those obtained by single crystal X-ray crystallography. Since the NOE is extremely sensitive to the modulation of the distance between the spins arising from internal motions, as well as

to the anisotropy of molecular reorientations, this methodology has led to detailed information on internal motions, conformational flexibility, local order parameters, exchange between chemically inequivalent sites and anisotropic reorientations of the molecules, some of which features are correlated to their biological functions. The field is growing rapidly with the help of modelling software, molecular mechanics calculations, development of newer experimental protocols such as isotopic labelling of spins (^{13}C and ^{15}N), measurement of J -coupling between heteronuclei, leading to conformational information, and the utilization of information contained in cross-correlations.

Symbols

$e^2Qq_{zz}h^{-1}$	quadrupole coupling constant
I	nuclear spin quantum number
I_B	ionic character of a bond
q_p	the electric field gradient produced by one unbalanced p electron
q_{zz}	electric field gradient (EFG) at a quadrupole nucleus
U_p^b, U_p^t	unpaired p-electron density of a bridging and terminal, halogen, respectively
η	asymmetry parameter
γ	Sternheimer antishielding factor

The NQR frequencies for the various nuclei vary from several kHz up to 1000 MHz. Their values depend on quadrupole moments of the nucleus, the valence electrons state and the type of chemical bond in which the studied atom participates. Using the NQR frequencies, the quadrupole coupling constant (QCC) and asymmetry parameter (η) can be calculated with either exact or approximate equations, according to the spin of the nuclei. For a polyvalent atom, the NQR frequencies depend on the coordination number and hybridization. The NQR frequency shifts for a single-valent atom in different environments can be classified as follows:

1. The greatest shifts of the NQR frequencies are determined by the valence electron state of the neighbouring atoms and can reach 1200–1500%. The changes of the NQR frequencies depend on ionic character, and for example for chlorine the lowest frequency corresponds to a chloride ion, whereas the highest corresponds to the chlorine atom in ClF_3 .
2. Changes within the limits of one type of chemical bond (with the same kind of atom) can reach 40–50%. Thus the frequency changes of C–Cl bonds vary from 29 to 44 MHz.
3. The range of possible shifts of the NQR frequencies is reduced to 10–20% when only one class of compound is studied. In this case the shifts are determined by the surroundings and donor–acceptor properties of the substituents. For example, for halogen substituted

benzenes, the changes of the frequencies for the C–Cl bonds are about 9%, for C–Br bonds ~12% and for C–I bonds ~18%.

4. The changes of NQR frequencies caused by the occurrence of intramolecular and intermolecular interactions lie within the limits of 3–40%.
5. The shifts of NQR frequencies caused by crystal field effects in molecular crystals reach a maximum of 1.5–2%. However within a series of similar compounds this effect, as a rule, does not exceed 0.3%.

Such classification of NQR frequency shifts allows the determination of structural non-equivalencies from NQR spectra. Understanding how the frequency shifts depend on chemical non-equivalence and how they are determined by distinctions in distribution of electronic density in a free molecule is very important. Moreover, crystallographical non-equivalences are observed, and are a result of distinct additional contributions of the crystal field to the electric field gradients at a nucleus. It is obvious that the division of structural non-equivalencies into molecular and crystal types is not relevant in coordination and ionic crystals, in which there are no individual molecules. NQR, being highly sensitive to subtle changes in electron density distribution, provides diverse information on the structural and chemical properties of compounds.

Molecular Structure Studies Using NQR

When applied to structural investigations, NQR spectra may prove an effective tool for the preliminary study of crystal structure in the absence of detailed X-ray data. Such parameters as spectroscopic shifts, multiplicity, spectroscopic splitting, resonance line width, the temperature dependence of resonance frequencies and relaxation rates all afford useful structural information and provide insight into the factors determining the formation of certain structural types.

The violation of chemical equivalence of resonance atoms due to a change in chemical bonding, such as, for example, dimerization in group IIIA halogenides, leads to a significant splitting of the spectroscopic multiplet caused by a difference in the electronic structure of bridging and terminal atoms.

Crystallographic Structures

For crystallographically non-equivalent atoms the corresponding components of the electric field gradient (EFG) at the respective sites differ from each other in magnitude and direction due to the crystal field effect. This generally includes a contribution to the EFG of electrostatic forces between molecules, dispersion forces, intermolecular bonding and short-range repulsion forces. Physically non-equivalent sites differ from each other only in the direction of the EFG components, their magnitudes being identical. To distinguish between such sites, Zeeman analysis of the NQR spectrum is required.

The intensities of spectroscopic lines are also important. They reflect the relative concentration of resonance nuclei at certain sites although one also has to take into account the transition probabilities and lifetimes of the energy states of the system investigated. The correspondence between the number and intensities of frequencies and the number of non-equivalent sites occupied by a resonant atom in a crystal lattice is very helpful in a preliminary structure study made with the use of NQR.

NQR single-crystal Zeeman analysis can provide information about special point positions occupied by the quadrupole atoms. This Zeeman analysis determines the orientation of the EFG components with respect to the crystal axes, which essentially facilitates the most difficult and time-consuming stage of X-ray analysis. **Table 1** gives a comparison of the angle values between the crystal axes and the EFG z -axis at the chlorine atoms in 1,3,5-trichlorobenzene (determined by the two methods).

As one can see from **Table 1** the angle values obtained by the two methods show rather good numerical

agreement. To illustrate more completely the type of structural information that can be obtained by NQR spectroscopy we consider in more detail an NQR study of BiCl_3 , whose structure is known. Two chlorine atoms are involved in bridging to two other Bi atoms while another chlorine atom is involved in bridging to only one other Bi atom. The ^{35}Cl and ^{209}Bi NQR parameters of BiCl_3 measured by means of the single-crystal Zeeman method are listed in **Table 2**.

The assignment of ^{35}Cl resonances is unambiguous owing to direct correspondence of the lower frequency line of double intensity to the two Cl atoms which are crystallographically nearly equivalent. The asymmetry parameter for the chlorine atoms has been determined, using the zero-splitting cone. According to the results the BiCl_3 crystal belongs to the Laue symmetry of D_{2h} and therefore to the orthorhombic crystal class. The Cl(1) and Bi atoms occupy special point positions in the lattice since only two non-equivalent directions of the corresponding EFG components have been detected for them, while four orientations have been found for the EFG components at the site of Cl(2,3) atoms. The number of observed ^{35}Cl resonances suggests that the molecule possesses a mirror plane and therefore the centrosymmetric group P_{nma} . The lower frequency resonance of double intensity is then assigned to the chlorines out of the mirror plane while the higher frequency line corresponds to one lying in the mirror plane. The shorter (i.e. more covalent) bond length of the latter corresponds to the higher resonance frequency.

Another example is provided by the ^{35}Cl results for phosphorus pentachloride. In the gas phase this is known to be a trigonal bipyramid but the usual solid PCl_5 is likewise known to be an ionic crystal, $(\text{PCl}_4)^+(\text{PCl}_6)^-$. In accordance with this, and the detailed crystal structure, there are four resonances at high frequency that correspond to the $(\text{PCl}_4)^+$ group and six at a lower frequency that correspond to the $(\text{PCl}_6)^-$ group (**Table 3**).

It has recently been observed that quenching of the vapour of PCl_5 gives rise to a new metastable crystalline phase which can be preserved essentially indefinitely at low temperatures. The ^{35}Cl spectrum of this has two low frequencies, corresponding to the axial chlorine atoms, and three identical higher frequencies, corresponding to the equatorial substituents, which is strong evidence that

	18.76	Bridging

this new phase is the corresponding molecular solid. Another example is taken from the chemistry of antimony pentachloride. It is known that the molecule of antimony pentachloride at 210 K has a trigonal bipyramid structure, and at 77 K it is a dimer. In **Table 3** the experimental ^{35}Cl NQR frequencies and their assignment to equatorial and axial chlorine atoms are given. In the dimer molecule, bridging chlorine atoms have much lower NQR frequencies, as in dimer molecules of group IIIA compounds. From **Table 3** it is also clear that in the monomer the NQR frequencies of equatorial chlorine atoms are greater than the axial ones.

In the dimer, the ratio of ^{35}Cl NQR frequencies is in agreement with the results of *ab initio* calculations. In dimers of transition elements, such as NbCl_5 and TaCl_5 , the ^{35}Cl NQR frequencies of equatorial chlorine atoms are higher than those of axial, whilst those of bridging chlorine atoms are higher, on average, than those of terminal chlorines. A similar inversion of NQR frequencies in dimers of transition and non-transition elements is explained by a significant multiplicity of the metal-halogen bonds and hence by electron transfer from p-valent orbitals of the halogen atoms to the vacant d-orbitals of the central atom.

The fact that the difference between chemically non-equivalent atomic positions is readily revealed by NQR spectroscopic splitting may be utilized to identify geometric isomers. Octahedral complexes of tin tetrachloride, $[\text{SnCl}_4 \cdot \text{L}_2]$, exist as either *cis* or *trans* isomers. In the *cis* isomers the axial and equatorial non-equivalence produces considerable splitting in the NQR spectra. In the *trans* complexes, all four chlorine atoms are chemically equivalent with identical electron density distribution. Splitting in the NQR spectra of these isomers arises therefore from the crystallographic non-equivalence of the chlorine positions. Indeed, the observed NQR splitting of two complexes (**Table 4**) provides evidence for the *cis* configuration of $[\text{SnCl}_4 \cdot (\text{OPCl}_3)_2]$ and the *trans* configuration of $[\text{SnCl}_4 \cdot (\text{NC}_5\text{H}_5)_2]$, which is confirmed by X-ray data.

Table 4 ^{35}Cl Quadrupole resonance frequencies and asymmetry parameters of some $[\text{SnCl}_4 \cdot 2\text{L}]$ and $[\text{SbCl}_5 \cdot \text{L}]$ complexes

Complex	$\nu^{35}\text{Cl}$ (MHz)	η (%)	Assignment
$[\text{SnCl}_4 \cdot (\text{NC}_5\text{H}_5)_2]$	17.644	15.4	—
	17.760	15.4	—
$[\text{SnCl}_4 \cdot (\text{OPCl}_3)_2]$	19.030	11.7	Equatorial
	19.794	11.1	Equatorial
	21.132	2.3	Axial
$[\text{SbCl}_5 \cdot \text{OPCl}_3]$	24.399	11.3	<i>Cis</i>
	25.821	2.5	<i>Trans</i>
	26.119	4.7	<i>Cis</i>
	27.314	4.9	<i>Cis</i>
$[\text{SbCl}_5 \cdot \text{NCCCl}_3]$	26.008	6.2	<i>Cis</i>
	26.313	10.3	<i>Cis</i>
	26.409	2.2	<i>Trans</i>
	27.297	11.2	<i>Cis</i>

However, it is not always possible to assign equatorial and axial chlorine atoms solely on the basis of the splitting of the ^{35}Cl NQR frequencies. For *cis* isomers, the ratio of the NQR frequencies of equatorial and axial chlorine atoms is fixed by several factors that determine the optimum crystal structure. Among these, the influence of donor molecules, L, is not a major contribution. In practically all structural investigations of complexes that exhibit this type of equatorial Sn-Cl bond it is usually noted that axial chlorines have lower relative NQR frequencies compared with equatorial atoms (**Table 4**). However, interpretation in structure terms is difficult because of the large values of the asymmetry parameters of chlorine atoms, which (**Table 4**) differ considerably for axial and equatorial atoms. On the other hand, donor ligands, L, influence the change in electron density of equatorial and axial Cl atoms and cause a relative lowering of frequencies of axial atoms in comparison with those of equatorial chlorines. Such a relation of frequencies in *cis* isomers is explained from the point of view of the 'mutual ligand influence' concept in non-transition element complexes. In *cis* complexes SnCl_4L_2 the interaction of $-\text{Sn}-\text{L}$ bonds will be stronger with Sn-Cl bonds which are in a *trans* position, than with *cis*-Sn-Cl bonds. For these complexes, the mutual ligand influence establishes the greater *trans* effect, and leads to a redistribution of the electronic density on the chlorine atoms. In $\text{SbCl}_5 \cdot \text{L}$ complexes (**Table 4**) to assign axial and equatorial chlorine atoms signals, even allowing for a knowledge of frequencies, splittings and asymmetry parameters, it is necessary in a number of cases to use the temperature dependences of NQR frequencies. In this case the NQR frequency is described by a square-law dependence: $\nu(T) = A + BT + CT^2$. A positive sign of the C coefficient indicates that an NQR frequency arises from an axial chlorine atom. Thus it appears that in some complexes the frequency of an axial chlorine atom lies above those of equatorial atoms. Apparently, in these

complexes the spatial influence of the donor molecules on the NQR frequencies of the equatorial chlorine atoms is dominant.

The width of the NQR signal also provides structural information. In molecular crystals of high order and purity the line width is not much different from the value determined from the sum of the spin-lattice relaxation and spin-spin relaxation times. In the majority of inorganic compounds, the lines are, however, inhomogeneously broadened by lattice imperfections such as defects, vacancies, admixtures and dislocations, so that their widths are mainly determined by the crystal inhomogeneity. A systematic study of spectroscopic shifts and broadening produced by a continuous change of the relevant sources of that broadening is an effective approach to the investigation of problems concerned with the distribution of mixtures over a matrix, the nature of their interaction with the matrix, the mechanisms of disorder and the local order in vitreous compounds.

Studies of Bonding Using NQR Spectra

The Townes-Dailey Approximation

The most widely used approach to provide a meaningful account of bonding trends within a series of related compounds is that formulated by Townes and Dailey for the interpretation of nuclear quadrupole interactions (NQI). The electric field gradient at a quadrupole nucleus (q_{zz}) arises mainly from electrons of the same atom. To a first approximation, it is possible to consider that the internal electrons will form a closed environment with spherical symmetry and, consequently, do not contribute to the EFG. Actually, polarization of the internal electrons is taken into account through the Sternheimer antishielding factor (γ_∞). However, if the comparison of NQI is only for the purpose of chemical interpretation and is not accompanied by discussion of their absolute meanings, the polarization of the internal electrons can be neglected. Among valent electrons, those that are on s orbitals with spherical symmetry do not contribute to the EFG and the main contribution is caused by p electrons; the contribution of d and f electrons is much less significant because of their greater distance from the nucleus and their smaller participation in hybridization.

The quantitative consideration of the contributions to the EFG results in expressions of the following type, applied here to nuclei of chlorine in chloroorganic compounds:

$$q_{zz}^{\text{Cl}} = [(1 - s^2 + d^2 - I_B - \pi) + I_B(s^2 + d^2)]q_{\text{at}}^{\text{Cl}} \quad [1]$$

where s^2 and d^2 are contributions from s and d orbitals to the hybridization of the chlorine atom bonding orbital, I_B is the ionic character of the bond (the chlorine atom

carries a partial negative charge) and $q_{\text{at}}^{\text{Cl}}$ is the gradient of p electron density on the chlorine atom. The valent orbitals can be represented by somewhat modified expressions in that some treatments include the three nuclear p orbital populations, and the axes x , y and z are usually defined so that the z -axis coincides with the bond direction of the considered halogen or with an axis of symmetry in the molecule. These approaches can be more convenient for discussing bonding and the contribution of lone pair electron orbitals.

On the basis of the above interpretation NQI can be unequivocally represented in terms of the population of orbitals. Actually, NQR spectroscopy allows the determination, at best, of two parameters (e^2Qqb^{-1} and η) and in many cases ($I = \frac{3}{2}$) only e^2Qqb^{-1} can be obtained. However, the above-mentioned eqn [1] contains four parameters (s , d , I_B , π) which cannot be determined from one or two experimental parameters. It is therefore necessary to include approximations, which neglect the d orbital participation in hybridization, and also, in some cases, p bonding and to consider that the s orbital hybridization is a small contribution and remains constant in a series of compounds. Thus changes of e^2Qqb^{-1} are directly related to bond ionic character or p electron charge transfer in the case of a hydrogen bond.

In the case of nitrogen, whose nucleus has a spin $I = 1$, the situation is more favourable, as the experiment allows the determination of both the nuclear quadrupole coupling constant and the asymmetry parameter, and it is possible to make conclusions about sp hybridization, if the molecular geometry is known. However, the meaning of nuclear NQI for ^{14}N p electrons is not known with as much accuracy as for chlorine, bromine or iodine, but the estimation of a 9–10 MHz contribution can be considered reliable, as it is based on the analysis of a large number of experimental data. An even more difficult situation is the case of the antimony atom, for which very little reliable NQI data exist.

Donor-Acceptor Interactions

In addition to interpreting experimental NQI values in terms of orbital populations, a role is also played by structural, dynamic and simple contributions, which change the NQI such that their experimental meanings differ from those expected for a hypothetical molecule or complex in an isolated condition at rest. In the case of molecular complexes there is an additional contribution which results in NQI changes caused by a change in hybridization from a change in the donor and the acceptor molecule geometry. A typical example is given by MX_3 complexes, where M is a group IIIA or VB element and X is a halogen or methyl group. With complex formation, the X–M–X angle and appropriate hybridization both change, and these result in changes in NQI

interpretation even in the absence of any charge transfer. This complicates unequivocal interpretation of experimental NQR data.

It is necessary to answer the question: are the shifts of the NQR frequencies caused by a transition from a pure, non-complexed mixture of initial substances to a complex, or because of a charge transfer or for other reasons? This rather important question depends on several factors. With a small charge transfer the NQR frequency shifts are defined mainly by crystal or solid-state effects, which are caused by distinct effects in the crystal environment of molecules as the result of the transition from individual components to the complex (crystal electrical field, intermolecular interactions, thermal movement); the complexation shifts can reach several hundred kHz (in the specific case of a resonance on a chlorine nucleus a shift of the order 200 kHz is typical). When the observable shifts have larger values (one to several MHz) they cannot be considered as caused by crystal effects and it is then possible with confidence to attribute them to electronic effects arising from a charge transfer. However, it is necessary to take into account other contributions, such as hybridization changes. The hybridization change accompanying deformation of a flat AlMe_3 molecule to a pyramidal form formally results in an NQI change on the aluminium atom, even if there is no electron population change or change in ionic character of the bonding orbitals; thus, the shift of the NQR frequency in this case can be determined as having both a charge and a hybridization contribution.

A more difficult situation exists when, in the free compounds, there are strong intermolecular interactions: the perturbation of these interactions by complex formation can result in an increased NQI in a complex which contradicts the usual, simple prediction of an NQI reduction upon transition to a complex. Such situations are met in complexes of mercury halogenides such as $\text{HgBr}_2 \cdot \text{dioxan}$ and $\text{HgI}_2 \cdot \text{dioxan}$. More complete interpretation of the experimental results can be achieved if in a complex there is present a number of quadrupole nuclei; this allows a comparison of shifts for each of them. In addition, there is often useful structural data available from X-ray diffraction. Finally for an estimation of a relative role of the various contributions to observable NQR frequency shifts, one can resort to theoretical calculations.

Intermolecular Interactions

Another example arises in the situation where a quadrupole halogen atom makes a symmetrical bridge between two metal atoms, which is often the case in polymeric metal halides of composition MX_n ($n = 3-5$). Dimers of metal halides, e.g. AlCl_3 , GaBr_3 , TaCl_5 , SbCl_5 or $[\text{Al}_2\text{Br}_7]^-$, have thus been attractive for NQR investigators, because of

Figure 1 (a) Spatial structure of MeX_3 type halides with two bridging bonds. (b) The same structure projected onto the plane of bridging bonds. The directions of the main axes of the EFG tensor on the bridging halogen atoms are marked, in the case when $\zeta < 109^\circ 28'$.

the differences between the resonance frequencies of bridging (X_b) and terminal (X_t) halogen atoms. The dimers have structures with either two bridging $\text{M}-\text{X}_b-\text{M}$ bonds of about equal length, as in GaBr_3 , or two bonds of significantly different length, as in complexes of oxygen donor ligands with mercuric halides, or one bridging bond as, e.g. in the aluminium heptabromide anion $[\text{Al}_2\text{Br}_7]^-$. **Figure 1** presents the structure of one type of symmetric bridging dimeric halide.

The spatial structure of the MX_3 -type dimer is shown in **Figure 1a** whereas **Figure 1b** presents the same structure projected onto the plane of the bridging bonds. The halogen atoms involved in the bridges are, together with metal atoms (M), in one plane which is perpendicular to the plane of the other terminal halogen atoms (X_t) and the metal atoms.

Analysis of the Zeeman splitting of the NQR spectra of halides of non-transition metals from group IIIA of the periodic table permits a determination of the directions of the main axes of the EFG tensor on the bridging halogen atoms. These directions are marked in **Figure 1b**. The axis of the greatest gradient of the electric field on the bridging halogen atom is perpendicular to the plane that contains the metal atoms and the bridging halogen atoms. The same axis, but on the terminal halogen atoms, lies along the metal-halogen bond. The orientation of the main axes of the EFG tensor in the case of other types of bridging dimeric halides is similar.

We have indicated that the NQR frequencies of the bridging halogen atoms in non-transition metal compounds are lower than those of the terminal atoms and

Table 5 NQR spectral parameters of some non-transition and transition metal dimer halogenides

			173.633		
NbCl ₅	13.290	58.8	7.330	—	101.3
NbBr ₅	105.850	58.8	59.500	—	101.3
WBr ₅	114.580	44.9	81.660	—	98.6

that this relationship is reversed in the case of transition metal compounds. **Table 5** includes the NQR frequencies of the bridging and terminal halogen atoms, the values of the EFG asymmetry parameter for the bridging and terminal halogen atoms, as well as the angles at the bridging atoms (see **Figure 1b**) for some non-transition and transition metal dimers.

X-ray structural and electron diffraction data indicate that, independent of the nature of the central metal atom, the length of the bridge is always greater than the distance between the terminal atoms. In non-transition metal compounds the effective negative charge on the bridging halogen atoms is smaller than that on the terminal atoms. The opposite situation is found in transition metal halides. In these compounds the effective negative charge on the bridging atoms is greater than that on the terminal ones. The explanation for this lies in the nature of the metal valence shells (p-d transfer). In the framework of the Townes and Dailey theory this means an effective lowering of the resonance frequency owing to the decrease in the p_x and p_y orbital population of the terminal halogens.

Figure 2 presents a correlation found by the linear regression method between the values of unpaired p-electron densities for the bridging (U_p^b) and terminal (U_p^t) halogen atoms for a large number of compounds. The existence of these correlations is connected with the influence of the p-electron distribution on NQR frequencies, and the bridging and terminal halogen atoms are connected through the central atom, which acts as a buffer. One can see from **Figure 2** that the experimental points can be divided into two groups, corresponding to non-transition and transition metal compounds. This is in good agreement with the difference in NQR frequencies for the bridging and terminal halogen atoms for all the compounds studied. As a consequence, the unpaired electron density differs for the compounds of both groups, although U_p^b increases with increasing U_p^t for all compounds studied. The observed correlations are approximate, which points to the influence of other factors,

**Figure 2** U_p^b versus U_p^t for halogen atoms in halides of transition (o) and non-transition (●) metal elements.

such as crystallographic uncertainty and the position of the molecules in the unit cell of the crystal.

Charge Distribution in Biological Molecules

NQR spectroscopy can be also used to provide detailed information on the structure and conformation of biologically active systems. It offers a unique possibility of determining the quadrupole coupling constants and, as a consequence, effective charges, and in this way allows a determination of the electronic structure of the molecule. NQR spectroscopy appears to offer a powerful tool for the investigation of various chemical effects in the solid phase of many nitrogen-containing compounds. Analysis of the quadrupole coupling constants of nitrogen atoms allows an estimation of the electron density distribution on the nitrogen nuclei and enables the analysis of charge distribution in chemical bonds involving nitrogen.

For example, the effect of substitution at the 1-H position of the 2-nitro-5-methylimidazole [2] ring can be analysed (**Table 6**). Hitherto, different imidazole derivatives have been studied by ^{14}N NQR, by the

continuous wave method, by ^{13}C NMR and ^{35}Cl NQR (pulse methods). However, the problem of the effect of a substituent at the 1-H position on the electron distribution in 2-nitro-5-methylimidazole [2] derivatives has not been considered. The results of NMR-NQR double resonance studies on a series of imidazoles (Table 6) are collected in Table 7.

As follows from the data in Table 7, the introduction of NO₂ and CH₃ at positions 2 and 5 of the imidazole ring, respectively, leads to an increase in nuclear quadrupole coupling constants on both nitrogens of the ring and a decrease in the value of this parameter on the nitrogen from the NO₂ group. Results of a bond population analysis carried out according to the

Townes–Dailey method for imidazole and its derivatives are displayed in Table 8.

According to the assumed notation, n_{NC} and n_{NR} stands for the population of N–C and N–R bonds, n_a stands for the lone pair population of an N atom, while π is the π -electron density. A comparison of the data collected in Table 8 shows that in the case of a 3-substituted nitrogen atom, the lone pair electron density and NR bond population increase with increasing length of a substituent at 1-H position in the imidazole ring, both at 193 and 269 K. The substitution of an NO₂ group at the 2-position and a methyl group at the 5-position of the imidazole ring leads to an insignificant redistribution of electron density (of the order of 2%) relative to that in pure imidazole. Only the introduction of a substituent at the 1-H position of the ring causes considerable changes. Similarly for a 2-substituted nitrogen, the bond population changes in a characteristic way – the π -electron density and population of the N–C bond decrease with elongation of the substituent at 1-H position of the imidazole ring (Table 8). Interestingly, a qualitatively similar but much more effective phenomenon is the electron redistribution on the nitrogen atoms of the NO₂ groups. Therefore it can be concluded that, in the case of 2-nitro-5-methyl derivatives of imidazole, with increasing length of the chain of the aliphatic substituent at the 1-H position of the imidazole ring, the electron density of the π -orbital and σ -bond of the 2-substituted atom, as well as the π -orbital and σ -bond of the NO₂ group towards the 3-substituted nitrogen, undergoes redistribution. Of essential importance is the character of substituents, i.e. CH₂CH₂OH and CH₂CH₂OCOCH₃ groups are electron density acceptors, while for

1H-imidazole and 1-acetylimidazole, the opposite tendency was observed, i.e. the π -electron density and the population of the σ -bond increased. The results also indicated that the effect of temperature on the bond populations in the imidazole derivatives studied is negligible.

The 4-*N*-derivatives of cytosine [5], R-substituent R = H, CH₂Ph, CH₂CH₂Sh, CH₂CH₂Ph and naphthalene, have aroused significant interest mainly because of their biological significance. 4-*N*-methyl and 4-*N*-acetylcytosine have been found in nuclei acids as rare bases. The results of the analysis of bond populations for cytosine and its derivatives performed according to the Townes–Dailey theory are described below. On the NH nitrogen, the changes in electron density distribution induced by substitution are insignificant. The symmetry of charge distribution at the NH nitrogen in 4-*N*-thioethylcytosine is the lowest while in 4-*N*-naphthalenecytosine it is the highest. On the other hand, the greatest value of the z -component of the EFG tensor was detected in the vicinity of the NH in pure cytosine while the smallest was in naphthalenecytosine, which implies that the electrons are drawn away from NH by the system of bonds depending on the substituent. Thus, it can be concluded that the introduction of a substituent at the amine group of cytosine at 4-*N* does not cause any changes when the substituent contains a chain such as CH₂CH₂ which separates the aromatic system from the cytosine ring. However, when the aromatic system is separated only by one CH₂ group, or is not separated at all, there occurs a strong inductive effect which is responsible for drawing π -electron density from the NH nitrogen. For a 2-substituted nitrogen the symmetry of charge density at $-N=$ is 50% lower. This is if one compares that of 4-*N*-phenylmethylcytosine with that of 4-*N*-thioethylcytosine, and about 20% lower than that of 4-*N*-naphthalenecytosine. On the other hand, the quadrupole coupling constant and thus the z -component of the EFG tensor at the $-N=$ nitrogen, is much higher in the derivatives whose substituents are not separated by the CH₂CH₂ chain. The difference between the population of the NC bond for pure and substituted

cytosine is small, -0.0001 for 4-*N*-thioethylcytosine but as great as 0.132 for 4-*N*-phenylmethylcytosine, which is still much less than the difference between the populations of σ and π bonds. Such a situation indicates that the changes in σ -bond population are dominant. In 4-*N*-naphthalenecytosine the change in π -electron density is dominant. This implies that $-N=$ in phenylmethylcytosine and naphthalenecytosine plays the role of a buffer. In 4-*N*-phenylmethylcytosine and 4-*N*-naphthalenecytosine the electron density of a free electron pair at the nitrogen NHR is significantly delocalized. The electron density on the NH bond in 4-*N*-naphthalenecytosine, 4-*N*-phenylmethylcytosine and 4-*N*-thioethylcytosine relative to that in pure cytosine changes by 0.053 , 0.038 and 0.005 , respectively, while for 4-*N*-phenylethylcytosine there is no change. Thus, the amine group, which acts as a π -electron acceptor in the majority of molecular systems, becomes the electron donor in phenylcytosine and naphthalenecytosine. The aromatic rings which usually compensate changes in electron density in cytosine act as electron acceptors. When the aromatic substituents are separated by the CH₂CH₂ chain, the density redistribution is reduced, which is in agreement with the tendency observed for chlorobenzenes. Investigations of cytosine and its derivatives have shown that the cytosine derivatives with an aliphatic substituent do not show an anticancer activity, but those with an aromatic substituent do. However, the mechanism of this activity has not been explained. The results suggest that in the search for anticancer drugs from the group of 4-*N*-cytosine derivatives, the choice should be those in which the aromatic substituents are not separated by a CH₂CH₂ chain, whose presence induces a significant redistribution of π -electron density. The ¹⁴N NQR frequencies recorded for cytosine derivatives were practically the same at ambient and liquid nitrogen temperatures, which means that no essential redistribution of electron density occurs in this temperature range.

The ¹⁴N nucleus, because of its widespread occurrence in all types of systems (especially biologically active systems), is of particular interest in studying

electron density distribution, molecular reorientations and intermolecular time-dependent interactions. It seems that such studies will acquire more and more importance in the future and will occur more frequently, especially with the availability of double resonance spectrometers and new data processing techniques such as the maximum entropy method. The examples discussed do not, of course, exhaust the potential of NQR as a tool for structure and chemical bonding. These are only simple illustrations of the applied aspects of NQR spectroscopy.

Application of NQR to the Detection of Explosives, Contraband etc.

The increasing use of plastic explosive and drugs has found experts and research facilities scrambling for new detection methods. One of these 'new' methods is NQR. In the 1990s a number of researchers around the world began to reconsider NQR as a possible solution for the detection of plastic explosives and started developing it specifically for bomb and narcotics detection. The non-invasive nature of NQR (closely connected with the absence of magnets) gives it some advantages over other methods.

Pulsed-RF NQR produces single, or nearly single, peak signals at specific frequencies that depend on the specific bond environment surrounding an element in a given compound, usually a crystalline solid. Because the resonance frequency is almost unique to each compound, NQR exhibits great specificity for analytes such as explosives and narcotics. The most useful elements to monitor by NQR are ^{14}N , ^{35}Cl and ^{37}Cl . Most high explosives contain 30–40% N and a large number of drugs such as cocaine and heroin are prepared as chloride salts. Most pure explosives such as RDX, HMX, TNT, C-4 are crystalline or semicrystalline compounds embedded in a polymer matrix, rather than pure polymeric compounds, so that they are immobilized and relatively ordered and as such give good NQR. Of course liquids and polymers are too disordered to give an NQR signal, although some monomers have shown detectable resonances.

NQR can be also used to differentiate between explosives, narcotics and benign nitrogen-containing compounds such as polyurethane foam or nylon. False alarms from these compounds are not a problem for NQR, whereas they might be for neutron activation or other generic nitrogen-detecting methods. It is well known that commercial and military explosives are physical mixtures of pure explosive compounds with some additive plasticizer or binder. Because NQR is so compound-specific, physical additives do not interfere with the signal for a target compound so NQR can be used to identify explosives that are not in a pure form. Moreover, it does not matter what form the explosive or drug is in – whether it

be tin sheets or small pellets. NQR may eventually be used to detect bombs or narcotics with spatial resolution, in the same way as X-ray metal detectors.

NQR is inherently less flexible than NMR but when it works it is extremely attractive because of its specificity. NQR can work with slurries, aggregates and possibly even emulsions, as long as the molecular dynamics are slower than the NQR method time scale (the MHz range). The ongoing use of NQR as analytical tool for measuring solid-state phase transitions and order-disorder in materials may also be of interest.

Summary

NQR is not as extensively useful at present as NMR spectroscopy. The best results on light nuclei, such for example as those on ^{27}Al nuclear coupling constants in mineral samples, have been made using NMR. Here, the changes in the NMR spectra were considered as a function of the orientation of a single crystal in external magnetic field. NQR could, however, directly measure the same nuclear coupling constant data using either single crystals or an external magnetic field. NQR measurements possess high spectral resolution, precision, specificity and speed of measurements. The reason for the relatively limited practical application of NQR seems to lie in the lack of sufficiently sophisticated equipment.

NQR applications can be divided into four groups:

1. Studies of the electron density distribution in a molecule – changes in orbital populations under substitution, and complexation.
2. Studies of molecular motions – reorientations, rotations, hindered rotations.
3. Studies of phase transitions.
4. Studies of impurities and mixed crystals.

Nuclear quadrupole resonance (NQR) is a modern research method for the analytical detection of chemical substances in the solid state. NQR is a type of radio-frequency (RF) spectroscopy, and is defined as the phenomenon of resonance RF absorption or emission of electromagnetic energy. It is due to the dependence of a portion of the energy of the electron–nuclear interactions on the mutual orientation of asymmetrically distributed charges of the atomic nucleus and the atomic shell electrons, as well as those charges that are outside the atomic radius. Thus, all changes in the quadrupole coupling constants and NQR frequencies are due to their electronic origin. The nuclear electric quadrupole moment eQ interacts with the electric field gradient eq , defined by the asymmetry parameter η . Therefore the nuclear quadrupole coupling constant e^2Qq and the asymmetry parameter η , which contain structural information about a molecule, may be calculated from the experimental data. The main spectral parameters in NQR experiments are the transition frequencies of the nucleus and the line width Δf . In addition, measurement of the spin–lattice relaxation time T_1 , spin–spin relaxation time T_2 and line-shape parameter T_2^* (inversely proportional to Δf) is also of great value. These parameters must also be taken into consideration when choosing the experimental technique and equipment.

NQR Methods

In contrast to nuclear magnetic resonance (NMR) methods, NQR can operate without a strong external DC

magnetic field. This technique is known as ‘pure NQR’, or direct NQR detection, and has many advantages for some applications, such as identification of specific compounds and remote NQR. In turn, direct NQR detection techniques can be subdivided into two main areas: oscillator-detector methods [continuous wave (CW) and superregenerative techniques] and pulsed methods. At present the pulse method is the most widely used direct NQR method. The use of various multipulse sequences permits a considerable increase in the sensitivity, and a decrease in the duration of the experiment.

Besides direct methods of detection, indirect NQR detection methods have also been developed. As a rule, they are used at low frequencies or in cases when the concentration of quadrupolar nuclei is not high, i.e. when the sensitivity of the direct methods is not sufficient. For most experiments, when using these methods, a constant magnetic field is needed. To apply these methods, it is necessary for the sample to have two spin systems connected by dipole–dipole interactions. Indirect methods can be conventionally divided into double-resonance techniques and the cross-relaxation spectroscopy method.

A block diagram summarizing the composition of the main technologies for NQR methods is given in Figure 1.

Direct NQR Detection (Pure NQR) Techniques and Equipment

Direct methods are the basis of experimental methods in NQR. They are used in a wide frequency range from hundreds, sometimes even tens of kHz to hundreds of MHz. Historically these methods started to be applied earlier than indirect methods. The first observations of NQR were undertaken using CW and superregenerative techniques, which are simple and inexpensive. These methods and techniques were developed during the 1960s to 1980s. At present it is the pulsed techniques that are more widely used, as they permit a better sensitivity and are more convenient for measuring NQR parameters of the sample over a wide frequency range. The modern pulsed techniques use the latest signal processing methods, including fast Fourier transformation (FFT), digital filtering, and others.

Oscillator-Detector Methods

Continuous wave techniques

CW NQR spectrometers are based on the use of oscillator-detectors, which are built around the circuits of a marginal oscillator or a limited oscillator (Robinson oscillator). Such an oscillator-detector includes a tank circuit with a coil, into which the studied sample is inserted. When the frequency of the oscillator-detector coincides with the NQR frequency in the sample, the sample starts to absorb energy and the amplitude of oscillations in the circuit decreases. This change in the amplitude is detected on the output of the oscillator-detector. The sensitivity of such spectrometers can be high and depends on the Q -factor of the coil, on the filling factor and on the noise temperature of the oscillator. Normally these oscillator-detectors cannot work at high levels of RF voltages and require accurate tuning of the electric circuit parameters. To avoid saturation of the sample during the detection process, they use either frequency modulation or Zeeman modulation, usually bisymmetric. Frequency modulation is easier to perform from the technical viewpoint, but it has the drawbacks of giving base-line drift and spurious signals.

In the literature one can find many descriptions of CW NQR spectrometers and oscillator-detectors for

various purposes and frequency ranges. Particular interest is evoked by limited oscillators, which have a low noise level similar to that of marginal oscillators but do not need continual critical adjustment of circuit parameters. **Figure 2** shows a simplified block diagram of a CW spectrometer, containing an oscillator-detector with a Zeeman modulation system and a computer for signal processing and frequency control.

Superregenerative technique

Superregenerative oscillators (SRO) have been widely used as oscillator-detectors in the study of NQR because of their high sensitivity at high RF levels, reliability of operation and simplicity of construction. The phenomenon of NQR was discovered by Demelt and Kruger using a SRO spectrometer. SRO is actually an oscillator-detector, with oscillation periodically quenched either with the help of an external quench oscillator (quencher mode), or with the help of internal circuits (self-quenched mode). A high sensitivity of the SRO is provided during its coherent work, when the oscillations are not quenched completely, i.e. not to the level of noise. Besides, SRO performs very well in logarithmic mode, when RF pulses are built up to a limiting amplitude. Detection of the NQR signal in SRO occurs as follows. Using RF

Figure 1 Main categories of NQR experimental techniques.

Figure 2 Simplified block diagram of a CW NQR spectrometer.

pulses, the SRO excites an NQR signal in a sample. This signal, which occurs in the intervals between these pulses, is added up with the resilient voltage. In this case oscillations in the next pulse will start on a higher level of voltage and will reach the limiting amplitude sooner, i.e. the length of the pulse will increase. This change in the length of the RF pulses of the SRO is detected as the signal.

Usually the SRO has a number of significant disadvantages: (i) poor frequency stability; (ii) the RF spectrum contains components (sidebands) spaced at integral multiples of the quench frequency on either side of the fundamental frequency, each of them being capable of exciting the NQR signal; (iii) poor fidelity of line shape reproduction; and (iv) dependence of the centre frequency on the quench frequency. The sideband suppression is achieved by using the quench frequency modulation. The other disadvantages can be eliminated by using the phenomenon of frequency (or injection) and phase-locking. In this case the frequency stability of the SRO will be determined by the stability of the external locking oscillator. To stabilize the shape of lines of the detected NQR signal, phase-locking is used. A simplified block diagram of such an NQR spectrometer is given in **Figure 3**. The frequency locking of the SRO is done by introducing a small voltage from the external adjustable oscillator, which switches the SRO from the regime of noncoherent work to coherent. An injection signal can be introduced with the help of a small capacitor or by simply using the inductance of the connection. As the SRO frequency is determined by the frequency of the external oscillator, the frequency modulation is applied to that oscillator. In the mode of frequency locking the change of the capacity of the SRO circuit leads to a

change in the phase of the generator frequency, which causes a change in the line shape of the detected signal. Therefore to stabilize the shape of the NQR signal line on the output of the SRO, so-called phase locking is carried out, using an additional phase detector. Such a phase detector permits the control of a required phase shift between the SRO frequency and the external oscillator frequency by automatic tuning of the capacity of the SRO circuit.

Pulsed Methods

The essence of the pulse method approach consists of irradiating the spin-system by RF pulses with frequencies equal or close to the NQR transition frequency and followed by detection of signals induced by this spin-system. Direct pulsed NQR methods are of great interest for industrial, medical, chemical and biochemical investigations. They also seem to be an effective technique for detecting the presence of prohibited goods (narcotics), landmines and plastic bombs. This technique is very convenient and commonly used for the measurement of line widths and relaxation times. CW and SRO spectroscopy are quite inefficient with regard to measuring time and in particular for samples with long T_1 and short T_2 . Nowadays, CW and SRO spectrometers have almost completely been replaced by pulsed FFT NQR instruments.

Multipulse techniques, widely used in magnetic resonance, are also very common in NQR spectroscopy. They are effectively used for increasing sensitivity, reducing the duration of the experiment, and for measuring relaxation times in the sample. In NQR such well-known sequences as spin-echo, Carr-Purcell (CP), Meiboom-Gill-modified CP, spin-locking sequence and phase-alternated pulse sequences are widely used. There is a

Figure 3 Simplified block diagram of a frequency and phase-locked NQR spectrometer based on a SRO-type oscillator-detector.

large practical interest at present in pulse sequences of the steady-state free precession type (SSFP). The simplest version of this sequence is well known in NQR as 'strong off-resonance comb'. When certain requirements are complied with, these sequences give a stationary signal that does not die down while the sequence is in action. This method is very convenient for achieving fast coherent accumulation (averaging) of the signal.

Various modifications of the pulsed SSFP-type sequences have been developed or are being developed to increase sensitivity and eliminate some undesirable effects, such as intensity and phase anomalies. Typical results for ^{14}N responses to SSFP-type sequences in HMX ($\text{C}_4\text{H}_8\text{O}_8\text{N}_8$) are shown in **Figure 4**. To carry out multipulse experiments, the pulsed NQR spectrometer must have a programmable pulse generator with a variety of possibilities for changing pulse length and spacing, and a phase shifter, which permits a large variation of the phase of the RF pulse.

Now, pulse Fourier spectroscopy is the preferred experimental technique in NQR. It was made possible by the introduction of inexpensive computers and by the development of FFT algorithms. Note that the principles of Fourier spectroscopy are well developed and widely used in other fields of spectroscopy, including magnetic resonance, electron paramagnetic resonance etc. Several monographs are available on this subject. The reader is referred to the Further Reading section for details of Fourier spectroscopy, including its application in NQR. To illustrate the FFT method in pulsed spectroscopy,

Figure 5 shows a typical ^{14}N NQR spectrum of powder RDX ($\text{C}_3\text{H}_6\text{O}_6\text{N}_6$), obtained from a free induction decay (FID).

One of the most important characteristics of a wide-band and pulsed NQR spectrometer is its sensitivity. This is because, in most cases, the intensity of NQR signals is very low. It is especially true for the low-frequency range, less than 10 MHz, but is also significant for higher frequencies. Therefore it is necessary for the receiving system of the spectrometer to have a low noise factor and to ensure matching of its input impedance with the circuit. Without this matching the noise factor can increase considerably. The signal-to-noise (S/N) ratio can also be increased by increasing the Q -factor of the circuit. The S/N ratio is proportional to $\sqrt{Q}$, because with the increase in quality, the amplitude of the signal voltage increases Q times, while the effective noise voltage increases by $\sqrt{Q}$ only. However, with the increase of the quality of the circuit, transient processes known as 'ringing', after the irradiating signal, become longer. At low frequency the length of transient processes can reach hundreds of microseconds, which creates considerable difficulties for detecting the inductance signal and even spin-echo signals in samples with short T_2 and T_2^* times. The problem of ringing can be solved by several methods. Most often Q -switching is used, i.e. during transmission the Q factor is low, about 5–10, but during receiving it is high, typically >100 . In a number of practical applications of NQR, e.g. in remote NQR, or detection using large volumes, it is desirable to have a

Figure 4 The response from nitrogen-14 in a sample of HMX to the SSFP pulse sequence with offset -5 kHz . The resonance frequency is 5.301 MHz at 295 K .

Figure 5 A typical nitrogen-14 NQR spectrum of powder RDX at 297 K, obtained from a FID. The resonance frequency is ~ 5.193 MHz.

high Q -factor in the transmit regime as well. In this case methods of active damping of transient processes in the circuit are used, i.e. a short-term decrease of Q directly after the irradiation pulse. There are many descriptions of circuits for this purpose in the literature. Good results are achieved when short antiphase RF pulses are used immediately after pulses of RF irradiation. This effect is shown in **Figure 6**.

Besides ringing, transient processes in the receiver module can also impede the observation of NQR signals in both high- and low-frequency parts of the receiver. To eliminate this, it is possible to use wide-band amplifiers in the high-frequency part, and to close the input of the receiver and the input of the synchronous detectors and switch off the reference frequency transmission during the excitation pulse. High sensitivity of an NQR spectrometer is achieved when using optimum filtering, which corresponds best to the parameters of the detected signal. For this purpose Bessel and Butterworth filters are usually used. As different substances have resonance lines of different width, it is preferable to have a receiver with a variable bandwidth. Most often receivers of NQR spectrometers are built on the basis of super-heterodyne techniques. These techniques are very efficient for wide frequency band spectrometers operated at 10 MHz. At low frequencies though (0.5–10 MHz) straight receiver systems are successfully used too. They consist of an RF amplifier, synchronous detectors, low-pass filter and an output video amplifier. As a rule, the principle of quadrature detection is used in all these receivers. Digital receivers, where analogue-to-digital conversion is carried out either at the intermediate frequency, or directly on the resonance frequency, have recently become more

widely used. Evidently in the future this will be the most promising direction in the development of receiver systems of NQR spectrometers.

The system of exciting the NQR signal in a sample is also an important part of a spectrometer. Besides a power amplifier, it contains a means of generating RF pulses (gate), a programmable pulse generator (sequencer) and a stable variable oscillator (synthesizer). To form various multipulse sequences it is also necessary to use phase shifters. A standard block diagram for a pulsed NQR instrument is given in **Figure 7**.

In the literature more complicated NQR spectrometers with frequency conversion in both the receiver and the transmitter (irradiation) modules have been described. It should be noted that in wide-band NQR spectrometers several receivers and power amplifiers are used, each of them intended for work in a specific frequency range. Many laboratories involved in NQR research use spectrometers that are either home-made or made to order by specialized companies. However, companies specializing in the technology for magnetic resonance also often produce small batches of high-quality NQR equipment. For example, the equipment produced by Tecmag, Inc. (www.tecmag.com/NQR.html) is extremely good for carrying out the most complicated NQR experiments. It contains devices for forming all kinds of common and rarely used pulse sequences. It also contains such vital modules as a digital signal processor, a pulse programmer, a signal averager with complex memory, a special frequency synthesizer, a digital receiver and the latest model of a PC with specialized software.

The development of electronics and new experimental techniques has allowed the considerable broadening of the areas of practical application for pulsed NQR. Important NQR applications include the detection of drugs, landmines and plastic explosives based on signals from the nuclei of nitrogen and chlorine, in which the NQR signal at low frequencies of 0.5–6 MHz is detected. The weakness of NQR signals hinders further development of this method, especially in this frequency range. Two different NQR techniques are being applied to detect these substances, detection using large ordinary coils and remote detection using special coils (antennae). The first technique is used to scan packages. It is a development of ordinary pulsed NQR techniques for use with large volumes and cannot be utilized to detect samples beyond a certain distance from the spectrometer coil (e.g. landmines). At the same time, the remote NQR technique is more universal. However, besides extremely complicated highly sensitive receiving equipment, it requires the use of specific signal processing methods for eliminating external interference. It is also necessary to establish the required RF field at a definite distance from the coil. In remote NQR, special flat-surface coils of

Figure 6 An RF pulse in the NQR spectrometer coil: (a) without ring damping, (b) after ring damping.

various designs are used, with irradiating and receiving coils (antennae) sometimes separated.

Indirect NQR Detection Technique

The indirect NQR detection technique was developed as a result of wide interest in important chemical compounds containing light nuclei. As a rule, these are organic compounds that are interesting from the point of view of biology and medicine. As NQR frequencies of light nuclei are located in the low-frequency range (less than 1 MHz), the intensity of the signals from these nuclei when using direct techniques is very low. The indirect NQR technique permits high sensitivity for detecting many light elements, which is very convenient for locating unknown resonances. This technique cannot

replace completely the direct method for NQR detection, but is important as a complementary technique.

Double Resonance

The principle of double resonance (DR) consists of the detection of a weak signal from one type of nucleus when directly detecting changes in the strong signal from another type of nucleus. Thus, the studied sample must contain two types of nuclei, N_Q and N_P , with one of them (e.g. N_P) having a strong nuclear resonance signal. Spin systems N_Q and N_P must be connected by dipole-dipole coupling, so that the exposure of one system is reflected in the state of the other. Nuclei with a strong NQR signal could be used as the N_P nuclei, but most often nuclei with a strong NMR signal, e.g. protons are used for this purpose.

Figure 7 Block diagram of a pulsed NQR instrument.

The DR techniques allow the successful detection of the NQR signal from such nuclei as ^2H , ^{10}B , ^{11}B , ^{14}N , ^{17}O , ^{23}Na , ^{25}Mg and ^{27}Al , which can be present in biologically important molecules. The DR methods have developed and improved quickly, and now a whole range of methods has appeared. Usually DR methods for NQR are divided into the following main groups: DR in the rotating frame, DR in the laboratory frame, DR by level crossing, DR by continuous coupling and DR by solid-state effect. The areas and details of the use of these methods can be found in the reviews given in the Further Reading section. It should be noted that the choice of a specific method depends on the type of the studied nuclei and the parameters of the sample, with relaxation times of both spin systems being very important.

In spite of a wide variety of different DR methods, the main stages of the experiment can very briefly be described as follows, using the widely used concept of spin temperature in magnetic resonance. Initially the N_P spins are prepared in a polarized state. Then the polarization of the N_Q spins occurs through thermal contact between the two spin systems. Another method widely used is resonant heating of the N_Q spins by irradiating them with an RF field. As a result of the new thermal contact, the spin temperature of the N_P spins changes, and this change is then registered as the NQR signal.

The experimental equipment for NQR DR consists first of all of a spectrometer for detecting nuclear resonance signals from the nuclei of N_P . As a rule, this is an ordinary NMR spectrometer and a DC magnet, which permits the detection of FID signals with 90° pulses. In

addition, a DR spectrometer contains a sample-transfer system, an irradiating system (for the N_Q nuclei), a cryostat, a controlling and automatic signal processing unit, including a PC, and also some additional modules depending on the chosen methods of detection, e.g. a source of additional magnetic fields.

Figure 8 shows a typical block diagram of an NMR/NQR DR spectrometer. Such spectrometers require a special sample transit system. Systems of various design can be used for this purpose, including those with linear induction motors, step motors or compressed air systems. As a source of DC magnetic field, permanent magnets or electromagnets are used. Initially the sample is located in the field of this magnet, and the NMR signal is detected (in the P-coil), then the sample is transferred into the Q-coil, where it is irradiated with RF pulses at the frequency of quadrupole nuclei. After this, the sample is returned into the magnetic field, where the NMR signal is detected again. The change in the amplitude of the NMR signal detects the NQR. For some experiments an intermediate magnetic field can be used. It is also possible instead of the mechanical transfer of the sample from the magnetic field, to switch the field. For experiments in quadrupole (NQR/NQR) DR the external magnetic field need not necessarily be used. This refers to spin-echo DR, or DR in the rotating frame, for example.

Cross-Relaxation Spectroscopy Method

The cross-relaxation (CR) method is well known in magnetic resonance spectroscopy and can be successfully

Figure 8 Simplified block diagram of a double resonance (NQR/NMR) spectrometer.

Figure 9 Simplified block diagram of a cross-relaxation NQR spectrometer.

used for the detection of weak NQR signals in the low-frequency area in particular. A characteristic of this method is the absence of irradiation of the spin system at NQR frequencies. In principle this method can also be regarded as a version of DR. A block diagram of a spectrometer for implementing the method of CR spectroscopy is given in **Figure 9**. It includes an NMR spectrometer, a controlling unit for regulating the magnetic field, and a computer system. The experiment is

usually carried out in the following way. At first, as when using an ordinary DR method, the sample is acted on by a strong DC magnetic field, and NMR signals from the N_P nuclei are detected. Then the magnetic field is changed to satisfy the conditions of CR between the levels of the N_P and N_Q nuclei. If the conditions of CR are satisfied, the amplitude of the NMR signal detected at the end of the measurement cycle will change, and these changes are then registered as the NQR signal.

The Use of Amplifiers Based on a DC SQUID

One of the newer methods that permit effective detection of weak NQR signals at low frequencies is the use of amplifiers based on a DC superconducting quantum interference device (SQUID). The operation of this is based on the use of two superconducting phenomena: flux quantization and Josephson tunnelling. In fact a SQUID represents a flux-to-voltage transducer with a very low noise temperature as compared with regular amplifiers, which is particularly important for low frequencies. The SQUID can be used in various methods for NQR detection, including CW methods as well as pulsed methods. Also, a SQUID amplifier does not have an input resonance circuit, and therefore permits the detection of signals over a broad bandwidth, from close to zero. Readers interested in the principles of operation, design and specificity of application for SQUIDs can find more information in the literature, included in the Further Reading section. NQR spectrometers using SQUIDs are of great interest for many practical applications, particularly in areas where the use of indirect methods is complicated from the technical point of view. This technique is developing rapidly at present.

ν	NQR frequency
ν_L	Larmor frequency
$\rho(r)$	nuclear electric charge distribution

Introduction

Nuclear quadrupole resonance (NQR) offers a unique means for the study of structure, dynamics and chemical bonding in solids. A number of atomic nuclei possess nonzero electric quadrupole moments in the ground state. The interaction of a nuclear quadrupole moment with the local inhomogeneous electric field removes the degeneracy of the nuclear ground state. The transition frequencies between the nuclear quadrupole energy levels, which are typically in the MHz frequency region, depend on the nuclear quadrupole moment and on the electric field gradient (EFG) tensor at the nucleus. The electric quadrupole moment is a well-defined property of a nucleus in its ground state, whereas the EFG tensor depends on the electric charge distribution around the nucleus. The NQR frequencies thus indirectly provide valuable information on the local structure around the observed atom and its chemical bonding. Thermal motions in solids partially average out the EFG tensor, whereas thermal motions in isotropic liquids average the EFG tensor to zero. The temperature dependence of the NQR frequencies thus provides valuable information on the thermal behaviour of solids.

Nuclear constants and the natural abundance of naturally occurring quadrupolar nuclei are listed in **Table 1**.

The Hamiltonian

We start by considering a nuclear electric charge distribution $\rho(r)$ placed in an external inhomogeneous electric field with the potential $V(r)$. The origin, $r=0$, is at the centre of gravity of the nucleus. The interaction energy E is given by

$$E = \int \rho(r) V(r) d^3r \quad [1]$$

where the integral is taken over the volume of $\rho(r)$. When the electrostatic potential varies weakly over the nuclear electric charge distribution, it can be expanded in a Taylor series about the origin to give the familiar multipole expansion of the energy:

$$E = V(0) \int \rho(r) d^3r + \sum_k \left(\frac{\partial V}{\partial x_k} \right)_0 \int x_k \rho(r) d^3r + \frac{1}{2} \sum_{k,l} \left(\frac{\partial^2 V}{\partial x_k \partial x_l} \right)_0 \int x_k x_l \rho(r) d^3r + \dots \quad [2]$$

The first term is the energy of the nuclear 'monopole' and does not depend on its orientation. It is thus of no interest to us. The second term is the dipole contribution, which vanishes because a nucleus in its ground state has definite parity and therefore zero electric dipole moment. In fact all odd nuclear electric multipole moments vanish by the same argument. The strongest term representing the orientation-dependent energy of a nucleus is thus the third, quadrupole, term in eqn [2]. The symmetric traceless second-rank tensor $(\partial^2 V / \partial x_k \partial x_l)_0 = V_{kl}$ is called the electric-field-gradient (EFG) tensor. Introducing a symmetric traceless second-rank tensor Q_{kl} ,

$$Q_{kl} = \int (3x_k x_l - r^2 \delta_{kl}) \rho(r) d^3r \quad [3]$$

we may rewrite the quadrupole term E_Q in eqn [2] as

$$E_Q = \frac{1}{6} \sum_{kl} Q_{kl} V_{kl} \quad [4]$$

Here Q_{kl} are the elements of the nuclear electric quadrupole moment tensor. Equation [4] is of course a classical expression. A quantum-mechanical expression for the quadrupole Hamiltonian H_Q is obtained from eqn [4] by

replacing the tensor elements Q_{kl} by the operators $Q_{kl}^{(\text{op})}$:

$$H_Q = \frac{1}{6} \sum_{kl} Q_{kl}^{(\text{op})} V_{kl} \quad [5]$$

The degeneracy of the nuclear ground state with a spin I is $2I + 1$. H_Q may be treated as a small perturbation that at least partially removes the degeneracy of the nuclear ground state. To calculate the energies of the nuclear quadrupole energy levels and the corresponding NQR frequencies, it is necessary to evaluate the matrix elements $\langle I, m | H_Q | I, m' \rangle$. Here I is the nuclear spin and m and m' are the magnetic quantum numbers. To evaluate the above matrix elements of H_Q , it is necessary to evaluate the matrix elements

$$\langle I, m | Q_{kl}^{(\text{op})} | I, m' \rangle \quad [6]$$

of the quadrupole moment tensor. Using the Wigner-Eckart theorem, we may replace the matrix elements given by eqn [6] by the matrix elements

$$\begin{aligned} & \langle I, m | \tilde{Q}_{kl} | I, m' \rangle \\ &= \left\langle I, m \left| C \left(\frac{3}{2} (I_k I_l + I_l I_k) - \delta_{kl} I^2 \right) \right| I, m' \right\rangle \end{aligned} \quad [7]$$

of a symmetric, traceless, second-rank tensor $\tilde{Q}$ composed of the components of the nuclear angular

momentum vector I . We define a scalar constant eQ called the nuclear quadrupole moment as $eQ = \langle I, I | \tilde{Q}_{zz} | I, I \rangle$ and express the proportionality C as $C = eQ / I(2I-1)$. The quadrupole Hamiltonian may thus be expressed as

$$H_Q = \frac{eQ}{6I(2I-1)} \sum_{kl} V_{kl} \left[\frac{3}{2} (I_k I_l + I_l I_k) - \delta_{kl} I^2 \right] \quad [8]$$

The elements V_{kl} depend on the choice of the coordinate system. The simplest situation arises in a coordinate system where the coordinate axes point along the principal directions of the EFG tensor. In this coordinate system the EFG tensor is diagonal. Let us denote the three principal values of the EFG tensor as V_{XX} , V_{YY} and V_{ZZ} ($|V_{XX}| \leq |V_{YY}| \leq |V_{ZZ}|$) and the corresponding three principal directions as X, Y and Z . The three principal values of the traceless EFG tensor are not independent. They can be described by two parameters:

$$eq = V_{ZZ} \quad \text{and} \quad \eta = (V_{XX} - V_{YY}) / V_{ZZ} \quad [9]$$

The quantity eq is thus the largest principal value of the EFG tensor measuring its magnitude, whereas the asymmetry parameter η measures the departure of the EFG tensor from axial symmetry. The asymmetry parameter η ranges between 0 and 1. Let us further choose the principal axis Z as the quantization axis and rewrite the

quadrupole Hamiltonian as

$$H_Q = \frac{e^2 q Q}{4I(2I-1)} \left[3I_z^2 - I^2 + \frac{\eta}{2}(I_+^2 + I_-^2) \right] \quad [10]$$

The quantity $e^2 q Q$ divided by the Planck constant h is called the quadrupole coupling constant. It measures the magnitude of the nuclear quadrupole interaction. The NQR frequencies of a given nucleus depend on its spin I and on two parameters, $e^2 q Q/h$ and η , related to the EFG tensor.

In solid-state NMR of quadrupolar nuclei, H_Q often represents a perturbation of the Zeeman interaction. It is then natural to choose the quantization axis z along the direction of the external magnetic field and rewrite eqn [8] in a convenient form:

$$H_Q = \frac{eQ}{4I(2I-1)} [V_0(3I_z^2 - I^2) + V_{+1}(I_- I_z + I_z I_-) + V_{-1}(I_+ I_z + I_z I_+) + V_{+2}I_-^2 + V_{-2}I_+^2] \quad [11]$$

Here

$$V_0 = V_{zz}, \quad V_{\pm 1} = V_{xz} \pm iV_{yz}$$

and

$$V_{\pm 2} = (V_{xx} - V_{yy})/2 \pm iV_{xy}$$

Nuclear Quadrupole Energy Levels and Resonance Frequencies

It is obvious from eqn [10] that H_Q mixes the states with $\Delta m = 2$ when $\eta \neq 0$ and the quantization axis points along the Z principal axis of the EFG tensor. We shall from now on assume that the quantization axis points along the Z principal axis of the EFG tensor and expand the eigenstates $|\psi\rangle$ of H_Q in the representation of the eigenstates $|I, m\rangle$ of I_z . The set of states $|I, m\rangle$ can first be divided into two subsets: (a) $|I, I\rangle, |I, I-2\rangle$, etc. and (b) $|I, I-1\rangle, |I, I-3\rangle$, etc.

Each eigenstate of H_Q is represented either by the states of the subset (a) or by the states of the subset (b). H_Q is also invariant to time inversion. Let $|\psi, t\rangle$ be an eigenstate of H_Q . Owing to the time-inversion symmetry of H_Q the state $|\psi, -t\rangle$ obtained after the inversion of time is also an eigenstate of H_Q with the same energy as $|\psi, t\rangle$. A state $|I, m\rangle$ transforms under the time inversion into the state $(-1)^{I-m} |I, -m\rangle$. In the case of an integer spin nucleus the states $|I, m\rangle$ and $|I, -m\rangle$ belong to the same subset of states and $|\psi, -t\rangle$ is generally equal to $|\psi, t\rangle$ multiplied by a phase factor. The energy levels are thus nondegenerate, except for $\eta = 0$. In the case of half-integer spin nuclei the states $|I, m\rangle$

and $|I, -m\rangle$ belong to two different subsets of states and $|\psi, -t\rangle$ is different from $|\psi, t\rangle$. The energy levels are generally doubly degenerate. This is called Kramers degeneracy. The inhomogeneous electric field thus completely removes the degeneracy of the nuclear ground state only for integer spin nuclei when $\eta \neq 0$. In case of a half-integer spin nucleus with a spin I , we observe only $I + 1/2$ doubly degenerate nuclear quadrupole energy levels.

We shall first consider nuclei with an integer spin 1, 2 and 3. In all these cases the energies of the nuclear quadrupole energy levels can be calculated analytically.

Spin 1

The energies E of the three nuclear quadrupole energy levels and the expansion coefficients c^m of the corresponding eigenstates $|\psi\rangle = \sum_m c^m |1, m\rangle$, in the representation of the eigenstates of I_z are given in **Table 2**.

The upper energy level in the case of $\eta = 0$ is doubly degenerate and only one NQR frequency, $\nu_Q = 3e^2 q Q/4h$, is observed. For a nonzero η , the three nuclear quadrupole resonance frequencies ν_+ , ν_- and ν_0 ($\nu_+ \geq \nu_- > \nu_0$) are

$$\begin{aligned} \nu_+ &= \frac{e^2 q Q}{4h} (3 + \eta) \\ \nu_- &= \frac{e^2 q Q}{4h} (3 - \eta) \\ \nu_0 &= \nu_+ - \nu_- = \frac{e^2 q Q}{2h} \eta \end{aligned} \quad [12]$$

The energies of the nuclear quadrupole energy levels and the NQR frequencies as functions of η are shown in **Figure 1**.

None of the NQR transitions is generally forbidden except for special orientations of the radiofrequency magnetic field. The NQR line at $\nu = \nu_+$ vanishes when the resonant radiofrequency magnetic field points perpendicularly to the principal direction X . Similarly, the NQR line at $\nu = \nu_-$ vanishes when the resonant radiofrequency magnetic field points perpendicularly to the principal direction Y , and the NQR line at $\nu = \nu_0$ vanishes when the resonant radiofrequency magnetic field points perpendicularly to the principal direction Z . In a powder sample all three NQR lines can be observed, whereas in a single crystal the orientation dependence of

the intensity of the NQR lines may be used to determine the orientation of the principal axes of the EFG tensor in a crystal-fixed coordinate system. The quadrupole coupling constant is usually calculated from the NQR frequencies as $e^2 q Q / h = 2(\nu_+ + \nu_-)/3$, and the asymmetry parameter η is equal to $\eta = 3(\nu_+ - \nu_-)/(\nu_+ + \nu_-)$.

Spins 2 and 3

The energies of the nuclear quadrupole energy levels and expansion coefficients c^m of the corresponding eigenstates of H_Q in the representation of the eigenstates of I_z , $|I, m\rangle$ for spins 2 and 3 are given in **Table 3** and **Table 4**, respectively.

Nuclei with an integer spin larger than 1 are seldom observed in practice. **Table 3** and **Table 4** are therefore included only for completeness.

Spin $\frac{3}{2}$

As seen from **Table 1**, a half-integer nuclear spin is much more common than an integer nuclear spin. Nuclei with a half-integer spin are often observed in practice. As already mentioned, the nuclear quadrupole energy levels of the half-integer spin nuclei are generally doubly degenerate. The two eigenstates of H_Q , $|\psi_+\rangle$ and $|\psi_-\rangle$, corresponding to the same doubly degenerate energy level are generally expressed as

$$\begin{aligned}
 |\Psi_+\rangle &= \sum_{k=0}^{I-1/2} c^k |I, I-2k\rangle \\
 |\Psi_-\rangle &= \sum_{k=0}^{I-1/2} c^k |I, -I+2k\rangle
 \end{aligned} \quad [13]$$

The energies of the nuclear quadrupole energy levels and the corresponding eigenstates of H_Q can in the

$$x = \sqrt{1 - \frac{\eta}{2} + \frac{\eta^2}{6}}, \quad y = \sqrt{1 + \frac{\eta}{2} + \frac{\eta^2}{6}}, \quad z = \sqrt{1 + \frac{5\eta^2}{3}}$$

general case ($\eta \neq 0$) be expressed analytically only for $I=\frac{3}{2}$ where

$$E_{\pm 3/2} = \pm \frac{e^2qQ}{4} \sqrt{1 + \frac{\eta^2}{3}} \quad [14]$$

and the eigenstates of H_Q are

$$\begin{aligned} |\Psi_{\pm 3/2}\rangle &= \sqrt{\frac{z+3}{2z}} \left| \frac{3}{2}, \pm \frac{3}{2} \right\rangle + \sqrt{\frac{z-3}{2z}} \left| \frac{3}{2}, \mp \frac{1}{2} \right\rangle \\ |\Psi_{\pm 1/2}\rangle &= -\sqrt{\frac{z-3}{2z}} \left| \frac{3}{2}, \pm \frac{3}{2} \right\rangle + \sqrt{\frac{z+3}{2z}} \left| \frac{3}{2}, \mp \frac{1}{2} \right\rangle \\ z &= \sqrt{9 + 3\eta^2} \end{aligned} \quad [15]$$

Only one NQR frequency ν_Q ,

$$\nu_Q = \frac{e^2qQ}{2b} \sqrt{1 + \frac{\eta^2}{3}} \quad [16]$$

is observed in this case. The quadrupole coupling constant e^2qQ/b and the asymmetry parameter η cannot be determined separately from the NQR frequency. The problem is usually solved by the application of a weak magnetic field or by the application of two-dimensional NQR techniques.

Spin $\frac{5}{2}$

The energies E of the three nuclear quadrupole energy levels are obtained from the secular equation

$$x^3 - 7(3 + \eta^2)x - 20(1 - \eta^2) = 0 \quad [17]$$

Here energy E is given as $E = (e^2qQ)/20x$, where x is a solution of the secular equation. The energies are usually labelled as E_m , where m is the magnetic quantum number which can be assigned to a given energy level when $\eta = 0$. The three NQR frequencies are labelled as $\nu_{5/2-1/2}$, $\nu_{5/2-3/2}$ and $\nu_{3/2-1/2}$ ($\nu_{5/2-1/2} > \nu_{5/2-3/2} \geq \nu_{3/2-1/2}$). The energies E_m and the NQR frequencies are shown in **Figure 2**.

The NQR line at the frequency $\nu_{5/2-1/2}$, $\nu_{5/2-1/2} = \nu_{5/2-3/2} + \nu_{3/2-1/2}$ is generally weaker than the other two NQR lines and cannot be observed when $\eta = 0$. The asymmetry parameter η is in practice calculated from the ratio $R = \nu_{3/2-1/2}/\nu_{5/2-3/2}$ which ranges from $R=0.5$ for $\eta=0$ to $R=1$ for $\eta=1$. When η is known, the quadrupole coupling constant can be calculated from any NQR frequency, most precisely from the highest NQR frequency $\nu_{5/2-1/2}$.

Spin $\frac{7}{2}$

The four energies E of the nuclear quadrupole energy levels are calculated from the secular equation

$$x^4 - 42\left(1 + \frac{\eta^2}{3}\right)x^2 - 64(1 - \eta^2)x + 105\left(1 + \frac{\eta^2}{3}\right)^2 = 0 \quad [18]$$

where $E = e^2qQx/28$. They are again labelled as E_m , $m = \frac{7}{2}, \frac{5}{2}, \frac{3}{2}, \frac{1}{2}$. The dependence of the energies E_m and of the NQR frequencies $\nu_{m-(m-1)} = (E_m - E_{m-1})/b$ on the symmetry parameter η is shown in **Figure 3**.

The three NQR frequencies corresponding to $\Delta m = 1$ give the strongest NQR signals. The NQR signals at the frequencies corresponding to $\Delta m = 2$ and $\Delta m = 3$ are also observed for large values of η , but their intensities are

Figure 2 Energy levels and NQR frequencies for $I = \frac{5}{2}$.

Figure 3 Energy levels and NQR frequencies $\nu_{m-(m-1)}$ for $I = \frac{7}{2}$.

lower than the intensities of the NQR lines corresponding to $\Delta m = 1$. As seen from **Figure 3**, the NQR frequency $\nu_{3/2-1/2}$ depends strongly on η , whereas the η -dependence of the other two NQR frequencies is weaker. The asymmetry parameter η is in practice determined either from the ratio $\nu_{3/2-1/2}/\nu_{5/2-3/2}$ or from the ratio $\nu_{3/2-1/2}/\nu_{7/2-5/2}$. When η is known, the quadrupole coupling constant is calculated from any NQR frequency, most precisely from the highest NQR frequency observed.

Spin $\frac{9}{2}$

The highest half-integer nuclear spin of a stable nucleus is $I = 9/2$. The energy E of a nuclear quadrupole energy

level is given as $E = e^2 q Q x / 24$, where x is a solution of the secular equation

$$x^5 - 11(3 + \eta^2)x^3 - 44(1 - \eta^2)x^2 + \frac{44}{3}(3 + \eta^2)^2x + 48(3 + \eta^2)(1 - \eta^2) = 0 \quad [19]$$

The energies of the nuclear quadrupole energy levels are again labelled as E_m , with m being the magnetic quantum number assigned to a quadrupole energy level when $\eta = 0$. The dependence of the energies E_m and of the NQR frequencies $\nu_{m-(m-1)}$ on the asymmetry parameter η is shown in **Figure 4**.

Figure 4 Energy levels and NQR frequencies $\nu_{m-(m-1)}$ for $I = \frac{9}{2}$.

The lowest NQR frequency $\nu_{3/2-1/2}$ also in this case exhibits the strongest dependence on η . The asymmetry parameter η is in practice determined from a ratio of the NQR frequencies, say $\nu_{3/2-1/2}/\nu_{5/2-3/2}$. When η is known, the quadrupole coupling constant $e^2 q Q/b$ is calculated from any NQR frequency.

Application of a Weak Magnetic Field: Zeeman Perturbed NQR

A weak static magnetic field is often used in NQR. In a powder sample it may cause broadening of an NQR line and consequently the disappearance of an NQR signal. In a single crystal a weak external magnetic field removes the degeneracy of the doubly degenerate quadrupolar energy levels. In the case of a half-integer quadrupolar nucleus, each NQR line splits into a quartet. The splitting depends on the orientation of the external magnetic field in the principal coordinate system of the EFG tensor. The orientation dependence of the splitting of the NQR lines gives the orientation of the principal axes of the EFG tensor in a crystal-fixed coordinate system and, for the case $I = 3/2$, also the value of the asymmetry parameter η . When I is integer, the external magnetic field slightly shifts the resonance frequencies. The orientation dependence of the frequency shift makes it possible to determine the orientation of the principal axes of the EFG tensor in a crystal-fixed coordinate system. In both cases the multiplicity of the resonance lines in nonzero magnetic field gives the number of magnetically nonequivalent nuclei in the crystal unit cell. Here we treat in detail only the situation for two nuclear spin systems $I = 1$ and $I = \frac{3}{2}$.

Spin 1

The Hamiltonian is

$$H = H_Q - b\nu_L(\mathbf{I}\mathbf{n}) \quad [20]$$

Here H_Q is given by eqn [10], $\nu_L = \gamma B/2\pi$ is the Larmor frequency of a nucleus in the external magnetic field B and $\mathbf{n}$ is a unit vector in the direction of B . We assume that the second term in eqn [20] may be treated as a perturbation and that $\nu_L \ll \nu_0$. The eigenstates of H_Q and their energies are given in **Table 2** for the case of $I = 1$. The expectation value $\langle \psi | I | \psi \rangle$ for any non-degenerated eigenstate of H_Q is identically equal to zero when I is integer. The first-order perturbation corrections of the energies are thus equal to zero. The lowest-order nonzero terms are thus the second-order terms. Let us denote the resonance frequencies of H as ν_+^* , ν_-^* and ν_0^* . Using second-order perturbation theory, we obtain

$$\begin{aligned} \nu_+^* &= \nu_+ + \nu_L^2 \left\{ \frac{1}{\nu_0} - \sin^2(\theta) \left[\left(\frac{1}{\nu_0} - \frac{2}{\nu_+} \right) + \left(\frac{2}{\nu_+} - \frac{1}{\nu_-} \right) \sin^2(\theta) \right] \right\} \\ \nu_-^* &= \nu_- + \nu_L^2 \left\{ -\frac{1}{\nu_0} + \sin^2(\theta) \left[\left(\frac{1}{\nu_0} + \frac{1}{\nu_+} \right) + \left(\frac{2}{\nu_-} - \frac{1}{\nu_+} \right) \sin^2(\theta) \right] \right\} \\ \nu_0^* &= \nu_0 + \nu_L^2 \left\{ \frac{2}{\nu_0} - \sin^2(\theta) \left[\left(\frac{2}{\nu_0} - \frac{1}{\nu_+} \right) + \left(\frac{1}{\nu_+} + \frac{1}{\nu_-} \right) \sin^2(\theta) \right] \right\} \end{aligned} \quad [21]$$

Here θ is the angle between the unit vector $\mathbf{n}$ and the principal axis Z of the EFG tensor, whereas ϕ is the angle between the projection of $\mathbf{n}$ on the X - Y plane and the principal axis X . It is clear from eqn [21] that the magnetic shifts of the NQR frequencies depend on the orientation of the external magnetic field with respect to the principal axes of the EFG tensor. In general in a magnetic field an NQR line splits into more lines. The multiplicity of the resonance line gives the number of crystallographically equivalent but magnetically nonequivalent positions of the studied atom in the unit cell. The crystallographically equivalent nuclei occupy positions where the principal values of the EFG tensor are equal. The magnetically nonequivalent sites differ in the orientation of the principal axes of the EFG tensor. An orientation dependence of the frequency shifts makes it possible to determine for each nuclear position the orientation of the principal axes X , Y and Z in a crystal-fixed coordinate system.

In the case of a low value of η with $v_0 \ll v_+$, v_- when the lowest NQR frequency v_0 may be comparable to the Larmor frequency v_L , the first-order perturbation calculation gives

$$\begin{aligned} v_{\pm}^* &= 3K \pm \sqrt{\eta^2 K^2 + v_L^2 \cos^2 \theta} \\ v_0^* &= 2\sqrt{\eta^2 K^2 + v_L^2 \cos^2 \theta} \end{aligned} \quad [22]$$

Here $K = e^2 q Q / 4b$. A splitting of the upper energy level, and consequently three resonance frequencies, is observed even when $\eta = 0$ if $B \neq 0$.

Spin $\frac{3}{2}$

The Hamiltonian is given by eqn [20] where the second term is treated as a perturbation. The energies and eigenstates of the unperturbed Hamiltonian H_Q are given by eqns [14] and [15]. By first-order perturbation theory, the upper energy level splits into two energy levels with the energies $E_{3/2} \pm b\delta_{3/2}$ where

$$\delta_{3/2} = \frac{v_L}{2z} \sqrt{(z+6)^2 + 3(z^2 - 6z - 18)\sin^2(\theta)} \quad [23]$$

Here $z = \sqrt{(9 + 3\eta^2)}$. The lower energy level splits into two energy levels with the energies $E_{1/2} \pm b\delta_{1/2}$ where

$$\delta_{1/2} = \frac{v_L}{2z} \sqrt{(z-6)^2 + 3(z^2 - 6z - 18)\sin^2(\theta)} \quad [24]$$

The NQR line splits a magnetic field into four lines. In a crystal a set of four lines is observed for each magnetically nonequivalent atomic site. From the orientation dependence of the splitting it is again possible

to determine the orientation of the principal axes of the EFG tensor in a crystal-fixed coordinate system.

In practice, NQR spectroscopists often locate zero splitting where the frequency of two inner resonance lines is equal to v_0 . This happens when $\delta_{3/2} = \delta_{1/2}$ or, consequently,

$$3 \cos^2(\theta_0) - 1 + \eta \sin^2(\theta_0) \cos(2\phi) = 0 \quad [25]$$

For zero η , zero splitting is observed when $\mathbf{B}$ lies on the surface of a cone around the principal axis Z with the angle $\theta_0 = -B$, $Z = 54.44^\circ$.

For nonzero η , the directions of the external magnetic field which leave an unsplit component at v_0 form an elliptical cone around the Z axis. The angle θ_0 is maximum when $\phi = 0^\circ (\mathbf{B} \perp Y)$ and minimum when $\phi = 90^\circ (\mathbf{B} \perp X)$. From an experimentally determined elliptical cone it is then easy to find the directions of the principal axes of the EFG tensor. The knowledge of $\theta_0(\phi = 0^\circ)$ and $\theta_0(\phi = 90^\circ)$ makes it possible to calculate the asymmetry parameter η :

$$\eta = \frac{3[\sin^2 \theta_0(0^\circ) - \sin^2 \theta_0(90^\circ)]}{\sin^2 \theta_0(0^\circ) + \sin^2 \theta_0(90^\circ)} \quad [26]$$

Many of the features of the $I = \frac{3}{2}$ case also appear in cases of $I = \frac{5}{2}$, $\frac{7}{2}$ and $\frac{9}{2}$. However, in these cases the asymmetry parameter η is determined simply from the ratio of the NQR frequencies, whereas the external magnetic field is used to determine the number of magnetically nonequivalent nuclei in the unit cell and the orientation of the principal axes of the EFG tensor in a crystal-fixed coordinate system.

Nucleic Acids and Nucleotides Studied Using Mass Spectrometry

Mass spectrometry is a powerful tool for the characterization of biomolecules including nucleotides, oligonucleotides and nucleic acids. The advantages of mass spectrometry are high sensitivity, high mass accuracy and, more importantly, structural information. Historically, oligonucleotides and nucleic acids have proved difficult to characterize using mass spectrometry. Problems often arise with impure samples, low ion abundance for analysis owing to inefficient ionization processes and low mass accuracy for higher-molecular-mass compounds. Advances in the development of electrospray ionization and matrix-assisted laser desorption/ionization now permit the analysis of oligonucleotides and nucleic acids with high sensitivity and good mass accuracy. These improvements allow the use of mass spectrometry for the identification of unknown oligonucleotide structures and are suitable for applications focused on acquiring sequence information on the samples of interest.

Nucleic Acids and Nucleotides

Nucleic acids are high-molecular-mass biopolymers composed of repeating units of nucleotide (nt) residues (**Figure 1**). The three major constituents of a nucleotide residue are the heterocyclic base, a sugar and a phosphate group. The five most common heterocyclic bases are adenine (Ade), cytosine (Cyt), guanine (Gua), thymine (Thy) and uracil (Ura). Cytosine, thymine and uracil are classified as pyrimidine bases, and adenine and guanine are classified as purine bases. Adenine, cytosine, guanine and thymine are the major bases found in deoxyribonucleic acids (DNA), and adenine, cytosine, guanine and uracil are the major bases found in ribonucleic acids (RNA). Nucleic acids are identified as either RNA or DNA, depending on the identity of the sugar. The sugar is a 2'-deoxy-D-ribose in DNA and a D-ribose in RNA. The phosphate group is usually attached through the 5' or 3' hydroxyl groups of the sugar.

Mononucleotides are typically represented by a shorthand notation that identifies the sugar, the base and the number of phosphate groups. For example, dNMP represents any 2'-deoxynucleoside monophosphate, dCDP represents 2'-deoxycytidine diphosphate and GTP represents guanosine triphosphate. Unfortunately, this convention is rarely followed in the mass spectrometry literature,

where nucleosides and mononucleotides are denoted by their single letter base abbreviation and a preceding or following 'p' to represent the location of the phosphate group on the mononucleotides (e.g. dC, dCp, pT and T for 2'-deoxycytidine, 2'-deoxycytidine 3'-monophosphate, thymidine 5'-monophosphate and thymidine respectively). This designation may be a source of confusion for those not familiar with this nomenclature and care should be used whenever such designations are used, especially when one wishes to distinguish nucleobases, nucleosides and nucleotides.

Oligonucleotides are most commonly joined together through the 3' and 5' sites of each nucleoside by a phosphodiester linkage. The primary sequence of an oligonucleotide is by definition determined from the 5' to the 3' end. Usually the sequence is written in shorthand notation, using the single letter abbreviations for the nucleobases, e.g. 5'-d(pTCAG)-3' as in **Figure 2**. In the case where the base composition is known, but the primary sequence is not, the unknown sequence regions are enclosed in parenthesis, e.g. 5'-dACT(GGCT)AAT-3'. Oligonucleotides of a specific length are typically referred to as *n*-mers, where *n* is the number of oligonucleotide residues.

Modified nucleosides are designated in the overall sequence by their chemical symbol (e.g., Am for 2'-O-methyladenosine). Unknown modified nucleosides often are designated by an 'X' in the overall sequence. Modified linkages are generally identified by describing the type of modified oligonucleotide followed by the usual sequence notation: a methylphosphonate 10-mer d(ACACGTT-GAC) or a phosphorothioate 12-mer d(GCGCATATG-CGC). Occasionally, phosphorothiates are identified by an 's' internucleotide linkage, such as d(AsCsTsAsG).

Ionization and Mass Analysis

Mass spectrometric measurements of oligonucleotides and nucleic acids involve the determination of molecular mass, or of the masses of dissociation products of gas-phase ions, which can then be related to various structural properties, such as sequence. In either case, the crucial step lies in the conversion of liquid- or solid-phase solutions of the analytes into gaseous ions. Common ionization sources used in mass spectrometry for

Figure 1 Subunit structures of the major nucleotides from deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). T, C and U nucleobases are pyrimidine derivatives, and A and G nucleobases are purine derivatives.

Figure 2 Shorthand notations of oligonucleotides: (a) line notation of oligonucleotides, and (b) one-letter sequence notation.

nucleic acid and nucleotide experiments are fast-atom bombardment (FAB), electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI). FAB was historically the ionization method of choice, but has largely been replaced by ESI or MALDI. ESI- and MALDI-based methods have particularly aided the analysis of nucleic acids because these techniques

accomplish the otherwise experimentally difficult task of producing gas-phase ions from solution species that are both very highly solvated and highly ionic. Mass analysis of oligonucleotides and nucleic acids up to the 100-mer level has been demonstrated using ESI-MS. Molecular ions from significantly larger oligonucleotides (up to the 400-mer level) can be generated using MALDI-MS, but realistic mass analysis is limited to oligonucleotides and nucleic acids at the 125-mer level.

Fast-Atom Bombardment

Oligonucleotide samples used in FAB must be soluble in a liquid matrix and are spotted onto a probe tip. Matrices selected are liquids with low vapour pressures and include glycerol, or an equal volume mixture of dithioerythritol and dithiothreitol (the 'magic bullet' matrix). Oligonucleotide samples are typically prepared as saturated solutions in water, and are spotted on the probe tip with neat matrices, prior to instrument insertion. FAB-MS of oligonucleotides is typically performed on a sector or quadrupole mass spectrometer and is limited to oligonucleotides that are no greater than 5000 Da in mass (Figure 3).

Figure 3 Positive ion mode FAB mass spectrum using a double focusing sector mass analyser. The sample is dpC with piperidine in nitrobenzyl alcohol matrix. The parent ion mass, $(M+H)^+$, is 307.3 Da.

Figure 4 Negative ion mode ESI spectrum of *Escherichia coli* 5S rRNA treated with *trans*-1,2-diaminocyclohexane- *N,N,N',N'*-tetraacetic acid (CDTA) and triethylamine (TEA) additives.

Electrospray Ionization

ESI requires sample introduction in liquid form and thus is convenient for the analysis of oligonucleotides. Samples are introduced into the instrument through a narrow capillary into a strong electrostatic field. Mixtures of an organic solvent and water are used in ESI-MS of oligonucleotides. Typical organic solvents are isopropanol, methanol or acetonitrile. Oligonucleotide sample concentrations for ESI experiments are prepared at the micromolar and nanomolar levels depending on the type of electrospray apparatus utilized. A mass spectrum of an

oligonucleotide generated using ESI is characterized by a series of multiply charged negative ions that differ from one another by the removal of a single proton. The multiple charging effect from ESI-generated ions is advantageous for mass spectral analysis because mass analysers with limited upper mass ranges can be used (Figure 4).

Matrix-Assisted Laser Desorption/Ionization

For MALDI-MS, oligonucleotide samples are mixed with a UV-absorbing matrix, spotted on a sample plate,

Figure 5 MALDI-TOF mass spectrum, in negative ion mode, of dA_{10} in 2,4,6-trihydroxyacetophenone matrix. The parent mass is seen as both singly and doubly charged ions.

and allowed to air dry. The common oligonucleotide MALDI matrices are 3-hydroxypicolinic acid, 2,4,6-trihydroxyacetophenone and 6-aza-2-thiothymine. Sample solutions for MALDI are at the micromolar or nanomolar level, with only a small fraction of the sample utilized in the MALDI experiment. A MALDI-generated mass spectrum of an oligonucleotide typically contains a singly negatively charged peak at the mass of the deprotonated ion. The analysis of MALDI-generated oligonucleotides is limited to either time-of-flight (TOF) mass spectrometers, which have an extended upper mass range but limited mass accuracy, or Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometers, which have a limited upper mass range but high mass accuracy (Figure 5).

Measurement of Molecular Mass

In ESI, both DNA and RNA are typically converted to gas-phase negative ions. Although the ionization efficiency is different for different homopolymers ($dT_{10} > dA_{10} \approx dC_{10} \approx dG_{10}$), both these and mixed bases are readily detectable. In MALDI, both DNA and RNA can be converted into gas-phase positive or negative ions. The quality of mass spectra from MALDI analyses is profoundly influenced by base composition. Thus, polythymidylic acids are readily analysed, but polydeoxyguanylic acids are a distinct challenge and mixed-base oligomers represent an intermediate situation. As a consequence of the increased stability of the glycosidic bond in RNA, it is more readily analysed than DNA.

Relative molecular mass is an intrinsic molecular property, which, when measured with high accuracy, becomes a unique and unusually effective parameter for

characterization of synthetic or natural oligonucleotides. Mass spectrometry-based methods can be broadly applied not only to normal (phosphodiester) nucleotides but also to phosphorothioates, methylphosphonates and other derivatives. The level of mass accuracy will depend on the capabilities of the mass analyser used. Quadrupole and TOF instruments yield lower mass accuracies than sector or FT-ICR instruments. High mass accuracy is necessary not only for the qualitative analysis of nucleotides present in a sample but to provide unambiguous peak identification in a mass spectrum. For example, uridine monophosphate and cytidine monophosphate are separated by 1 Da (306.26 u, and 305.25 u, respectively) and oligonucleotides differing by the number of uridine and cytidine nucleotides may be difficult to distinguish in a mixture. In such cases, the confidence of assigning a putative oligonucleotide base composition from the molecular mass measurement is dependent on the type of mass analyser used.

In ESI, mass measurement errors of 0.03% and lower are typical and, with appropriate sample clean-up, values lower than 0.01% can be obtained routinely. In contrast, for MALDI, typical measurement errors are between 0.03% and 0.05% and, with use of internal standards, mass measurement errors on the order of 0.01% can be obtained for small oligonucleotides.

The primary challenge to accurate molecular mass measurements of oligonucleotides and nucleic acids is reduction or complete removal of salt adducts. In solution, the phosphodiester backbone is completely ionized at $pH > 1$ and the solvent acts as a dielectric shield to reduce the repulsive Coulombic charging. During the ionization process, this Coulombic protection is lost, which eventually results in the adduction of any cations that may be present in solution. These cations (usually Na^+) reduce the

polarity of this highly charged backbone, improving the production of gas-phase ions. It is these adducts that shift the centroid to higher values and limit the ability to determine molecular masses accurately.

Ammonium (or tetraethylammonium) are preferred salt forms for both ESI and MALDI. High-performance liquid chromatography (HPLC) purification is a suitable approach for sample purification, especially when ammonium buffers are used. Solvent additives, such as ethylenediaminetetraacetic acid and triethylamine, can also be added to the sample solution in ESI or MALDI to help alleviate the interference of alkali salt ions from the spectra (Figures 4 and 5). In MALDI, cation-exchange resin beads are effective at generating the ammonium salts of the oligonucleotides prior to mass analysis.

Determination of Nucleotide Sequence by Gas-Phase Sequencing

General Fragmentation Processes

Dissociation of oligonucleotides can occur as a result of the excess energy that is imparted to the analyte during the desorption/ionization process. This dissociation is relatively fast (i.e. timescales shorter than the total mass spectral analysis time), resulting in ions that are generally difficult to identify accurately. Electrospray ionization produces stable, intact molecular ions except when the source conditions are adjusted to impart excess translational energy into the analyte, leading to its dissociation in the electrospray interface region (so-called nozzle-skimmer dissociation, discussed below). Thus, most dissociations that are desorption/ionization-induced are seen only in MALDI or FAB spectra. There are essentially four differing timescales for desorption/ionization-induced dissociations: prompt, fast, fast metastable and metastable.

- Prompt dissociations occur on a timescale equal to or less than the desorption event.
- Fast dissociations occur after the desorption event, but before or at the beginning of the acceleration event.
- Fast metastable decays occur on the timescale of the acceleration event.
- Metastable decays occur after the acceleration event, during the field-free flight time of the ion.

In theory, dissociations occurring during any one of these timescales will generate fragment ions that could be used to determine the sequence of the oligonucleotide. In practice, unless certain instrumental parameters are manipulated, most of these fragments result in a broadening of the molecular ion peak with a concomitant loss of resolution and sensitivity.

Owing to these drawbacks and because such a method for sequencing provides little control over the extent of

fragmentation, there are few reports of using desorption/ionization-induced fragmentation to determine oligonucleotide sequences. Prompt fragment ions will be detected at their appropriate m/z values, using linear and reflectron time-of-flight mass spectrometers, with the reflectron geometry yielding higher resolution than the linear geometry, presumably owing to the interference of fast fragment ions in the latter case. Also, it is evident that formation of prompt fragment ions is matrix- and sequence-dependent, but is independent of the laser wavelength.

Figure 6 illustrates the possible fragments one might see during the dissociation of an oligonucleotide. B_1 , B_2 and B_3 represent nucleobases numbered consecutively from the 5'-terminus of the molecule. Fragment ions containing the 5'-terminus of the original molecule are labelled a, b, c and d, and differ by the site of bond cleavage along the oligonucleotide backbone. Fragment ions containing the 3'-terminus of the original molecule are labelled w, x, y and z, and, as the 5'-fragments, they differ by the site of bond cleavage along the oligonucleotide backbone. The sequence location of bond cleavage for the a-d and w-z fragment ions is denoted by a subscript reflecting the number of nucleobases remaining in the fragment ion (Figure 7).

Figure 6 Representative fragmentation pattern of oligonucleotides.

Figure 7 MALDI mass spectrum of d(CATCG) with 2,4,6-trihydroxyacetophenone as the matrix. The laser-induced fragment ions are labelled corresponding to the fragmentation nomenclature shown in Figure 6.

Intentional Dissociation Methods

Intentional fragmentation of oligonucleotides may be caused by several methods including nozzle-skimmer dissociation (NS), photodissociation (PD), and collision-induced dissociation (CID). Intentional fragmentation can be made to occur within or near to the ionization source, or within a specified region of the mass analyser. NS dissociation occurs in ESI-MS when the translationally excited molecular ion collides with the background neutrals that are present in the high-pressure ESI source interface. NS dissociation generates fragment ions similar to those found in traditional CID spectra for small ($n \leq 15$) oligonucleotides. NS dissociation can also be used to obtain sequence information on larger ($n \geq 50$) oligonucleotides. However, complete sequence information on oligonucleotides of this size is not possible using this technique. Infrared multiphoton dissociation (IRMPD) has been used to characterize the sequence of small and large oligonucleotides. As with NS dissociation, complete sequence information can be obtained for small oligonucleotides, but this technique does not yield complete sequence information from larger oligonucleotides.

Tandem Mass Spectrometry (MS/MS)

An important goal in the mass spectrometric analysis of oligonucleotides has been to develop methods to determine structural information (such as sequence) through the dissociation of a molecule in the gas phase and interpretation of the resulting fragmentation pattern. The development of FAB-MS increased greatly the ability to perform such sequence analysis. However, it was not until the later development and application of primarily ESI-MS (and to a small extent, MALDI-MS) that meaningful tandem mass spectrometry studies were performed on oligonucleotides. In general, the fragmentation patterns of oligonucleotides are similar in spite of the different ionization techniques or mass analysers used.

Mass accuracy is essential for sequencing of unknowns using MS/MS experiments. If the oligonucleotide length is known, possible combinations of the four nucleotides may be calculated corresponding to the parent ion mass, and reasonable fragment ions can be assigned. If the length of the oligonucleotide is not known, working with high mass accuracy can help to reduce the possible sequence combinations calculated to match the parent ion mass. This technique is powerful because the specific fragment ions for a specific molecule can be identified and interference from other ions is eliminated. MS/MS also helps to reduce the problem of increased combination sequences as a result of increased sample size. When using mass analysers such as FT-ICR-MS or quadrupole ion traps, subsequent collisions and mass

analysis (MSⁿ) may be conducted repeatedly, increasing the structural information obtained with each step.

Determination of Nucleotide Sequence by Solution-Phase Sequencing

Mass Ladders

The utility of any mass spectrometric sequencing method that relies on consecutive backbone cleavages depends on the formation of a mass ladder. The sequence information is obtained by determining the mass difference between successive peaks in the mass spectrum. In the case of oligodeoxynucleotides, the expected mass differences between successive peaks will correspond to the loss of dC = 289.25 u, dT = 304.26 u, dA = 313.27 u and dG = 329.27 u (all values are atomic mass-based). With oligoribonucleotides, the mass differences will be rC = 305.25 u, rU = 306.26 u, rA = 329.27 u and rG = 345.27 u (all values are atomic mass-based).

As is the case for all sequence determination methods that rely on the mass measurements of successive *n*-mers, oligodeoxynucleotides are easier to characterize owing to the relatively large differences in mass among the four oligodeoxynucleotide residues. The ribonucleotide residues, owing to the small mass difference between U- and C-containing nucleotides (a mass difference of only 1 Da), require a higher mass accuracy measurement to correctly distinguish U from C. Further, all mass ladder methods have a distinct advantage for sequence determination because it is the difference in two mass measurements that results in the desired information – the identity of the nucleotide residue. Because the accuracy of each individual oligonucleotide mass measurement is not critical, provided that the same bias exists for all ions detected, this procedure can be performed routinely on instruments with inherently lower mass accuracies; in particular, on TOF mass spectrometers.

Failure Sequence Analysis

One of the simplest methods for characterizing the chain length and sequence of synthetic oligonucleotides is the detection of failure sequences from the original synthesis step. This procedure takes advantage of the fact that automated solid-phase synthesis of oligonucleotides, especially those that contain modified internucleotide linkages such as methylphosphonates or phosphorothioates, is not 100% efficient. For example, the solid-phase synthesis of phosphodiester-linked oligonucleotides generally produces a yield of 99–100% for each synthesis cycle. Synthesis of a 10-mer at a 99.5% yield per cycle would result in an overall yield of 95.6%, with the remaining 4.4% being failure products that terminated

before completion of the synthesis. Synthesis of larger oligonucleotides, naturally, will result in lower overall yields. For example, the synthesis of a 50-mer oligonucleotide at the 99.5% yield per cycle level would result in an overall yield of only 78.2%; nearly one-quarter of the sample would be failure sequences.

One potential drawback to this method is the reduction in yield of the failure sequences of larger oligonucleotides. For example, assuming that the synthesis yield per cycle is 95%, the 5-mer failure product will be present in the final solution at a concentration four times greater than a 30-mer failure product. As the coupling yields increase, this difference becomes smaller. If the coupling yield increases to 99%, the 5-mer will be only 1.28 times as concentrated as the 30-mer. However, the total amount of failure sequence products will also decrease in this case. These factors place some upper limit on the size of the oligonucleotide that is amenable to sequencing and to the applicability of this approach for very efficient synthesis protocols.

Sequence determination of oligonucleotides by an analysis of the failure sequences is an extremely simple and straightforward method. The mass spectrum will contain a series of peaks that corresponds to the final product and to each one of the failure sequences, each of which differs in mass by the appropriate nucleotide residue value. The sequence of the oligonucleotide is determined in the 5' to 3' direction from the mass ladder of the synthesis failure products.

Exonuclease Digestion

The use of exonucleases to generate mass ladders of oligonucleotides that are suitable for analysis by mass spectrometry is now a standard method for sequencing small to moderate-length oligonucleotides. Unlike the failure sequence analysis method described above, this approach is suitable for the sequence analysis of naturally occurring oligonucleotides. Enzymes that hydrolyse the oligonucleotide consecutively from either the 5'- or 3'-terminus may be combined with unknown nucleotide samples and, over the reaction time, oligonucleotide ion signals are monitored by mass spectrometry. As the reaction progresses with the loss of one nucleotide at a time, the parent ion decreases in abundance and a 'mass ladder' is generated with each peak of lower mass corresponding to the sequential loss of a terminal nucleotide. Oligonucleotides up to the 40-mer level can be characterized readily by this approach.

Chemical Digestion

An alternative to the enzymatic approach is the use of chemical agents to cleave the original oligonucleotide

into smaller components for mass analysis. Although the number of applications of chemical digestion methods for sequence determination of oligonucleotides is far smaller than the number of applications of the failure sequence method or enzymatic approach, there are several important cases where neither of the latter two approaches is suitable for oligonucleotide analysis. These cases generally occur when the oligonucleotide backbone has been modified, such as in the case of antisense oligonucleotides, where modification is chosen specifically to reduce the susceptibility of the oligonucleotide to enzymatic digestion. The principles of analysis for the majority of the chemical digestion protocols are identical to those in failure sequence analysis and enzymatic digestion in that the goal is to generate a mass ladder of peaks that differ from one another by a nucleotide residue. As such, all of the general concerns for sequence determination by formation of mass ladders will apply to these methods.

We can classify chemical cleavages by their specificity for oligonucleotide base composition and/or linkage identity. Nonspecific chemical cleavages are reactions such as acid and/or base hydrolysis and alkylation reactions. In each of these reactions, the cleavage of the phosphodiester backbone does not depend on the base composition of the oligonucleotide. Acid hydrolysis is more specific for DNA, base hydrolysis is more specific for RNA and methylphosphonate-linked oligonucleotides, and alkylation is more specific for phosphorothioate-linked oligonucleotides. However, there is little to no base specificity for these chemical approaches.

The generation of a mass ladder of oligonucleotides for sequence determination using a chemical digestion approach can be complicated by the nonspecific nature of the chemical cleavage reaction. Any linkage site can potentially be cleaved by the chemical agent. If a single cleavage site is generated randomly for each oligonucleotide, then two sequence-specific fragments are produced, one from the 5'- and another from the 3'-terminus. If each of these fragments is detected in the resulting mass spectrum, then there is twice the necessary amount of information needed for the sequence to be determined. Although this additional information may facilitate sequence determination, especially if complete sequence coverage is unobtainable in any one direction, these two ion series can be a source of confusion.

Introduction

Nucleic acids are central molecules in all living organisms and perform a multitude of functions; DNA is the carrier of genetic information, and RNA is the transport molecule that relays the information stored in the genes to the ribosome for expression of proteins. RNA molecules can themselves carry genetic information (as in viruses) and possess catalytic activity (as in ribozymes or the ribosome). Indeed, RNAs of varied structures appear to be implicated in an ever-increasing number of cellular roles: regulation of gene expression, splicing, post-transcriptional modification, replication, and packaging of viruses. Furthermore, genomes contain a large number of previously undetected small noncoding RNAs, some of which have been shown to be involved in key regulatory roles, so-called riboswitches.

DNA can, besides the Watson–Crick double helix, adopt structures consisting of three or four strands, triplexes, and quadruplexes if strict sequence requirements are met. These structures occur within living organisms as well as the Watson–Crick duplex. Triplexes occur when triple-stranded H-DNA is formed and G-quadruplexes can arise when the G-rich telomere folds.

To get an understanding of the function of these nucleic acid molecules, it is essential to expand

knowledge of the structure and dynamics of these molecules and of their interactions. With its ability to yield structural information at the level of atomic detail, NMR spectroscopy is an efficient technique for the study of the polyanionic nucleic acids. The efficiency is highlighted by a search in the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank. Whereas only 13% of the protein structures deposited have been solved by solution NMR, almost 40% of the nucleic acid structures are NMR structures.

Nucleic Acid Structure

DNA and RNA are polymers built of four different units: the nucleosides adenosine, guanosine, cytosine, and thymine (DNA) or uracil (RNA). The basic scaffolds are the B-type helix for double-stranded DNA (dsDNA) and the A-type helix for dsRNA (**Figure 1**). Besides the canonical A-type helix, RNA presents a wide repertoire of structural variability with conformations ranging from single-stranded to complex tertiary structures when not Watson–Crick base-paired with a complementary strand. Furthermore, noncanonical base pairs, bulges, and internal loops may be embedded into and disrupt helical structure. This difference between DNA and RNA possibly stems from the different actions of these molecules in nature. Whereas DNA serves as an imperturbable entity preserving genetic information with high confidence, RNA is the transporter molecule interacting with other nucleic acids or proteins and thereby is in need of specific (nonhelical) structural motifs to present for recognition.

The geometry of a nucleotide is conveniently described by eight torsion angles. The glycosidic angle establishes the orientation of the nucleobase with respect to the sugar, the pseudorotation angle describes the puckering of the ribose or deoxyribose sugar, and six angles describe the conformation of the sugar–phosphate backbone.

Preparation of Nucleic Acids

NMR analysis requires samples in the milligram scale of oligonucleotide for analysis. Hence, the availability of robust schemes of synthesis is imperative for the success of NMR spectroscopy in the analysis of nucleic acids.

DNA oligonucleotides for NMR analysis are usually prepared by chemical synthesis using phosphoramidite chemistry on an automated synthesizer. With this method,

Figure 1 (a) The chemical structure of DNA and RNA. (b) The five nucleobases appearing in DNA and RNA. (c) The two common helix types for double-stranded DNA and RNA.

Figure 2 The principles of *in vitro* transcription with T7 RNA polymerase. rNTPs = ribonucleotide triphosphates; PAGE = polyacrylamide gel electrophoresis.

high quantities of DNA can be prepared at a fairly low cost. Likewise, RNA can be prepared using chemical methods, which works well for shorter oligonucleotides (<25–30 nucleotides) but leads to low yields for longer sequences. Rather, *in vitro* transcription using T7 RNA polymerase is preferred for synthesis of RNA oligonucleotides. The polymerase requires ribonucleotide triphosphates (rNTPs) and a DNA template for function (**Figure 2**). For synthesis of ^{13}C - or ^{15}N -labeled RNA, isotopically enriched rNTPs are commercially available at a reasonable cost. Using T7 RNA polymerase, nucleotide-specific labeled RNAs can be produced by mixing appropriate labeled and unlabeled rNTPs. However, if a specific segment of the oligonucleotide should be labeled, whereas the remainder is unlabeled, more advanced methods utilizing ligations are needed.

Resonance Assignment

The repetition of just four units makes the resonance assignment of nucleic acids more difficult than for proteins. The best dispersion is obtained for the aromatic (6.9–8.5 ppm) and anomeric protons (5.5–6.5 ppm). In RNA, the remaining protons of the ribose sugar are all situated in very similar chemical environments, and consequently, a very limited chemical shift dispersion is

encountered (3.8–5.2 ppm). The dispersion of sugar resonances is better in DNA as the C2' carbon is not bound to any electronegative atoms. Thus, the H2' and H2'' protons usually resonate between 1.6 and 3.0 ppm. The chemical shift dispersion in DNA allows unambiguous assignment of natural abundance samples, based on through-space nuclear Overhauser effect (NOE) contacts under the assumption of a given secondary structure (such as a right-handed B-type helix) (**Figure 3**). If the assumed secondary structure is wrong, inconsistencies will appear during the assignment procedure, and an alternative hypothesis has to be proposed. For DNA structures in which the secondary structure is largely unknown, as for some G-quadruplex structures, the assignment of unlabeled oligonucleotides might prove time consuming and requires spectra of nucleotide-substituted samples; guanosine to inosine substitutions are particularly useful in the case of G-quadruplexes.

With RNA, application of the through-space assignment principles developed for DNA is feasible for duplexes or hairpins up to approximately 14 nucleotides. For larger RNA molecules, resonance overlap precludes unambiguous assignment based entirely on NOE connectivities, and a ^{13}C - or ^{15}N -labeled oligonucleotide is required. Using isotope-labeled RNA, a through-bond assignment strategy is possible. A general assignment scheme will consist of four steps: (1) identification of

Figure 3 Stereoview of some short intra- and internucleotide distances in B-type dsDNA. The sequential H6/H8($n-1$)-H1' ($n-1$)-H6/H8(n) and H6/H8($n-1$)-H2'/H2''($n-1$)-H6/H8(n) pathways used in through-space assignments are indicated in red and blue, respectively.

Using the spectra shown in (b), the H2' and H3' protons are unambiguously assigned.

aromatic nucleobase spin systems and correlation of the imino and aromatic protons, (2) identification of sugar spin systems, (3) correlation between the spin systems in the nucleobase and sugar either by observation of an NOE contact between the H1' and aromatic protons or by direct through-bond correlation between H1' and the

glycosidic nitrogen on the nucleobase, and (4) correlation between sequential nucleotide spin systems either by observation of sequential NOE contacts between H1' and aromatic protons or by correlation with the phosphorus atom adjoining the nucleotides. A number of optimized multidimensional heteronuclear and isotope-filtered

NMR experiments exist to obtain the desired through-bond correlations (Figure 4). This strategy will work for uniformly labeled (i.e., all nucleotides are labeled) RNA molecules with a size up to approximately 40 nucleotides. Stepping above this threshold requires additional measures. At first, several samples with various types of non-uniform labeling (i.e., perhaps only C and G nucleotides labeled, and so forth) may aid the assignment. An alternative approach to reduce the crowding of spectra is to use nucleotides deuterated at specific positions. For very large molecules, this is an attractive possibility, as not only will the spectral complexity be reduced but exchanging protons with deuterium also decreases the line width owing to reduced dipolar interactions. For very large RNA molecules, complete assignment might not be possible. However, a wealth of information is accessible even though only some nuclei are assigned. For example, the assignment of imino protons, as these are fairly easily obtained, will contain information on the secondary structure and folding pattern of a molecule (see the following text).

Establishing the Secondary Structure

To establish the folding topology of a nucleic acid, it is essential to deduce the base-pairing pattern. The imino proton region of a ^1H NMR spectrum yields immediate information. The imino proton of a nucleobase is only observed if the proton is involved in a hydrogen bond and hence protected from exchange with the bulk solvent. Thus, the number of lines in the imino region of a

spectrum directly represents the number of imino protons involved in base-pairing. Besides this, the chemical shift of an imino proton yields information about the type of base pair. Watson–Crick base pairs tend to give resonances in the range 12–15 ppm, whereas other types of base pairs fall outside this range.

Once the base-pairing pattern is established, the secondary structure can be analyzed. Sequential NOE contacts between imino protons (inter- or intrastrand) will identify helical regions (Figure 5). In addition, nuclei located in a regular helical environment will display chemical shifts within a known range. Thus, the occurrence of chemical shifts within this helical range corroborates the formation of a helical structure. Particularly, the ^{31}P chemical shifts are sensitive to changes in the backbone geometry, as these chemical shifts, to a large degree, are determined by the α and ζ backbone angles, but the chemical shifts of ^1H , ^{13}C , and ^{15}N are also valuable reporters for changes in geometry. RNA molecules are by nature modular structures that can be decomposed into substructures consisting of locally stable A-type helices adjoined by nonhelical substructures such as bulges and internal loops. Just as the helical regions are identified by chemical shift, the nonhelical regions are also recognized by their chemical shift values.

Structural Parameters

After the secondary structure is established, one might choose to do a full three-dimensional structure determination. In this respect, usually four types of

Figure 5 The imino–imino region of a nuclear Overhauser spectroscopy (NOESY) spectrum of a dsDNA:LNA triplex (LNA = locked nucleic acid). Sequential imino–imino NOE contacts in the Watson–Crick duplex (green) and in the LNA strand (blue) are shown together with NOE contacts between the LNA strand and the duplex part of the triplex (red). These imino–imino contacts unambiguously define the formation of a triplex. parameters are pertinent. The chemical shift is the most easily determined parameter reporting on structure. Its use is, however, mostly for the identification of substructures as described previously. Nevertheless, chemical shifts, as very sensitive markers for structure, may also be applied for validation of structures or for selection of the most likely structures from an ensemble. The classical parameters used in all structure elucidations are scalar couplings, reporting on the torsion angles, and the NOE reporting on interproton distances. The NOE originates from dipole-dipole relaxation and is observed between nuclei closer than $\approx 6 \text{ \AA}$ in space. Scalar couplings and NOE contacts are local parameters and can very accurately define the local structure of a molecule. Residual dipolar couplings (RDCs) are introduced by partial alignment of the molecule, in which case the dipolar coupling is no longer averaged to zero by isotropic tumbling (**Figure 6**). RDCs contain an inherently different type of structural information, as compared to the other parameters described, as they report on the orientations of individual bond vectors with regard to the axes of the alignment tensor of the molecule. Thus, the RDCs provide the long-range or global structural information that is completely lacking in other types of structural data derived by NMR spectroscopy. Partial

alignment of the molecule is achieved by dissolving the biomolecules in an inert ordered medium. The ordered medium transfers some of its order to the solute molecules through a combination of steric obstruction and electrostatic interactions. Commonly used ordered media for nucleic acids are filamentous phages and *n*-alkyl-polyethylene glycol/*n*-alkyl-alcohol bicelles. The magnitude of the RDCs is controlled by the concentration of the ordered medium. The magnetic field itself spontaneously aligns nucleic acids owing to the magnetic susceptibility anisotropy of the nucleobases (**Figure 6**). The degree of alignment depends on the square of the magnetic field strength. Although the interaction between individual nucleobases and the magnetic field is diminutive, the constructive addition of magnetic susceptibility, as observed in a helix where nucleobases are lying in an ordered nearly coaxial array, increases the degree of ordering. Magnetic field ordering is most suited for larger nucleic acids.

Structure Determination

Once resonances are assigned and structural data extracted, the three-dimensional structure can be calculated.

Figure 6 (a) Partial alignment of nucleic acids using Pf1 phage, which transmit their order through a combination of steric and electrostatic mechanisms. (b) Spontaneous alignment due to constructive addition of anisotropic magnetic susceptibility tensors (χ) in the nucleobases of nucleic acids. At first, the NOE data are converted to distance intervals that should be included as pseudo-energy potentials in a refinement protocol. Usually, NOESY spectra are collected with different mixing times (often between 50 and 300 ms). NOE intensities can be converted to distance restraints in various manners. A simple method, the isolated spin-pair approximation (ISPA), is to calibrate the intensity against the intensity of a peak corresponding to a known distance (i.e., the H5–H6 cross peak from cytosine) and divide the NOE intensities into three or four categories: strong, medium, weak, and very weak, with corresponding distance bounds. Although simple, this method is rather inaccurate as spin diffusion is not accounted for. More accurate methods, taking spin diffusion into account, exist but are more elaborate and not often used. When using the ISPA with its intrinsic limitations, one should assign conservative distance bounds. The number of (structurally relevant) distance restraints is more important than the precision of restraints. The distance restraints should be as uniformly spread over the molecule as possible.

Scalar couplings can be transmitted to torsion angles through Karplus relationships. In nucleic acids, coupling constants are important for analyzing the ribose or deoxyribose sugar pucker and to determine the conformation of the sugar–phosphate backbone. Accordingly, restraints can be included in structure calculations.

Often, additional restraints are added in structure calculations, besides the experimentally derived ones. These restraints might be to impose a helical structure if chemical shifts point to this, to keep sugar–phosphate backbone angles within usual helical ranges, or to keep base-paired nucleobases within the same plane. However, care should be taken with such restraints, and if a structure can be calculated based entirely on observed data, this should be preferred.

For the actual refinement of the geometry, a force field is applied to describe the potential energy of the molecule. The NMR data, NOE distance restraints and dihedral angles based on scalar couplings, are added as pseudo-potentials adding zero energy to the force field energy whenever the restrained distance or angle is within the experimental bounds. A number of force fields exist, and for nucleic acids, the force fields implemented in the X-PLOR or AMBER suite of programs are most often used. There is no consensus as to the actual refinement protocol. However, one should take care that the protocol searches the conformational space adequately and that an ensemble as diverse as specified by the experimental restraints is calculated.

Generally, the inclusion of RDCs improves the convergence of calculated structures. However, the full potential of RDCs is revealed in their application in determination of global structural features where

Figure 7 Structure of the 77-nucleotide HCV IRES domain II. (a) Superposition of structural ensembles calculated without and with RDCs. Nucleobases are blue, and the ribose–phosphate backbone is pink. (b) Local superposition of domains IIb and IIa, respectively. scalar couplings and NOE contacts are of little use (Figure 7). As all measured RDCs report to a common reference, the alignment tensor of the molecule, the relative orientation of substructures such as A-type helices can be determined by finding the alignment tensors for each substructure, with subsequent reorientation of these structural elements until alignment tensors overlap.

Pushing the Size Limit

With a fully ^{13}C - and ^{15}N -labeled sample, resonance assignment is possible for RNA molecules of less than 45–50 nucleotides. When exceeding this limit, different measures have to be taken. The ‘divide and conquer’ approach has proven successful for the structural study of RNAs up to ≈ 100 nucleotides. In this approach, smaller thermodynamically stable structural elements are excised from the large RNA and studied individually. The structure of the large RNA is then calculated by data obtained from each of the substructures, combined with orientation data from the large molecule itself. To date, the largest RNA structure solved at high resolution is the 77-nucleotide domain II of the hepatitis C virus internal ribosome entry site (HCV IRES) (Figure 7). With the ‘divide and conquer’ approach, the design process in which the subdivision is conceived is very important, and utmost care should be taken to ensure that each of the substructures folds in the conformation relevant in the context of the larger RNA. Usually chemical shift comparison validates the approach as identical chemical shift values in the substructures and the large RNA do indeed guarantee similar folding patterns. A limitation of the ‘divide and conquer’ approach is that it is only applicable for molecules that can be subdivided into smaller domains that can be studied individually. Within this class of molecules are a number of extended RNA structures, but many biologically interesting RNA molecules fold with a complex tertiary fold where subdomains interact closely with each other, as seen in riboswitches, tRNA, and so forth.

NMR spectroscopy can, however, often offer a detailed characterization of biomolecular molecules or complexes, even without the need of a high-resolution structure. Using selective isotope labeling in both the ligand and the RNA, the intermolecular interactions between the purine ligands and the ligand-binding domains of the purine-responsive riboswitch RNAs have been characterized. The effect of posttranslational RNA modifications in a tRNA has also been investigated using easily measured imino N–H RDC data. A further example is the study of a minimal hammerhead ribozyme construct where two very different folding patterns were observed with and without Mg^{2+} ions.

Nucleic Acid Dynamics

Although structure provides a very important aspect of biomolecular function, the dynamics of a molecule is an integral part of a complete description. Indeed in some cases, conformational changes are interlinked with the molecule’s function. For example, ribozymes undergo conformational changes during their catalytic cycles, and riboswitches respond to changes in cellular signals by large-scale conformational rearrangement. The conformational dynamics that are important for biological activity occur over a wide range of timescales. Libration motions that allow molecules to sample multiple conformations with small energetic barriers occur on the picosecond to nanosecond timescale, whereas motions such as stem reorientations and base-pair take place on a slower microsecond to millisecond timescale. Dedicated NMR experiments are an excellent way to derive information on the internal motions of biomacromolecules on the picosecond to nanosecond timescale at atomic resolution using spin relaxation. The most widely used approach to obtain dynamical information on subnanosecond timescales involves analyzing transverse (R_2) and longitudinal (R_1) relaxation rates together with heteronuclear NOEs using the model-free formalism. This method is commonly used in protein systems but has only more recently been applied to nucleic acids, as a number of factors complicate such applications. Among these is the scarceness of N–H groups in nucleic acids. C–H groups could in principle report on motion at many more sites; however, ^{13}C spins pose challenges in both measurement and data interpretation owing to the presence of C–C interactions and sizable asymmetric chemical shift anisotropy tensors. Although NMR spectroscopic techniques can provide detailed information on amplitudes and timescales of internal motions, it is not possible to characterize the underlying motion. Combining NMR studies with molecular dynamics simulations might allow such characterization.

A recently introduced method is to study dynamics of nucleic acids using RDCs. RDCs are very favorable parameters for structure determination; they also report on the dynamics of molecules. Local motions on the submicrosecond timescale will attenuate an RDC. Thus, the observance of several attenuated RDCs within a segment of DNA or RNA will point to local mobility. Lacking NOE contacts or dedicated spin relaxation measurement can confirm the plasticity. As noted, the average orientation of helical domains may be obtained by superimposition of each domain’s alignment tensor frames. In addition to this structural information, the RDCs also contain information on the relative motions of the two domains and allow one to distinguish between fixed bends and interhelical flexibility.

Nucleic Acid Interactions

A first step in the study of interactions between molecules is to characterize the binding surface between them. With NMR, four methods are apparent. The simplest method is chemical shift perturbation. Spectra of an isotopically labeled molecule are recorded before and after addition of the unlabeled binding partner. Resonances that show chemical shift perturbation or line broadening indicate contact sites. This method cannot distinguish between direct contacts with the binding partner or changes in the structure in a region distant from the binding site caused by the interaction.

Saturation transfer from a bound ligand is observed through direct and short-range effects ($<6 \text{ \AA}$) within the binding surface. For RNA-protein interactions, it is

particularly advantageous that the $\text{H1}'$ protons in RNA resonate in a chemical shift range usually devoid of protein resonances. Thus, by saturating the $\text{H1}'$ protons selectively, the RNA binding surface on the protein can be identified.

If complete chemical shift assignments are available, collection of intermolecular NOEs allows a precise structure determination of the molecular interface. Isotope-filtered experiments may be used to identify intermolecular NOEs between labeled and unlabeled binding partners. Although this method can provide very detailed information on the binding surface, it is also time consuming. Furthermore, depending on the strength and type of the molecular interaction, the intermolecular NOEs may be attenuated or absent.

Incorporation of a site-specific spin label gives the opportunity to derive long-range distance data from

Figure 8 I-motif and G-quadruplex DNA structures. (a) The chemical structure of a hemiprotonated C:C^+ base pair. (b) Schematic view of a crisscross intercalated i-motif structure. (c) Molecular representation of an i-motif structure. (d) The chemical structure of a Hoogsteen base-paired G-tetrad. (e) Schematic view of a dimeric G-quadruplex structure. (f) Molecular representation of a G-quadruplex structure.

paramagnetic relaxation enhancement. A useful spin label for RNA is to couple the free radical 3-(2-iodoacetamidopropyl) to a 4-thiouridine base. The presence of a paramagnetic center enhances relaxation of nuclei within a 25 Å radius and is thus an attractive alternative to the measurements of NOEs that are normally not observed beyond a distance of 6 Å. For RNA–protein complexes, spin labeling of the RNA in several locations might generate sufficient distance restraints to define the location of the RNA and protein components.

For structure determination of RNA–protein complexes, distance data derived as discussed previously should be complemented with orientational restraints from RDCs to define the structure of the binding interface. In the refinement process, most often a refinement of each of the subdomain structures will be included to account for conformational differences and induced fit binding of the components involved.

DNA Structures Other Than Duplexes

DNA can exist in a number of secondary structures depending on the base sequence. Polypyridine:polypurine tracts are able to form triple helix structures where a polypurine oligonucleotide targets the Watson–Crick duplex in the major groove through the formation of Hoogsteen base pairs; G-rich DNA strands can form G-quadruplexes, four stranded structures built on a G-tetrad scaffold; and C-rich DNA strands form i-motif structures built of crisscross intercalated hemiprotonated C:C⁺ base pairs at low pH (**Figure 8**). NMR spectroscopy is again a versatile technique for studies of these molecules, whether at low or high resolution. For example, combined with other biophysical techniques such as circular dichroism, analysis of imino proton resonances, resonating between 10 and 12 ppm for G-tetrads, and their NOE contacts may establish the folding topology of a G-quadruplex. For a hemiprotonated C:C⁺ base pair, the imino resonance resonates between 15 and 16 ppm.

Thus, the equilibrium between Watson–Crick base-paired duplex and G-quadruplex/i-motif for G- and C-rich strands is easily studied by NMR spectroscopy. The procedure for resonance assignment is generally a similar through-space strategy, as for dsDNA. For G-quadruplexes, the correlation of imino and aromatic protons is essential to establish G-tetrad compositions, and natural abundance heteronuclear multiple bond coherence (HMBC) experiments are often used to this end. For slowly folding structures such as i-motifs and G-quadruplexes, the folding process or interconversion between different conformations may be studied using real-time NMR.

Symbols

B_0	applied magnetic field strength (flux density)
E_{AB}	energy of couplings interaction between nuclei A and B
J	spin coupling constant
T_1	spin–lattice relaxation time
T_2	spin–spin relaxation time
$W_{1/2}$	full width at half-height of NMR line
δ	chemical shift
ω	angular frequency of applied radiation
$\Delta\sigma$	shielding anisotropy
σ	nuclear shielding parameter
τ_0	molecular correlation time

Introduction

High-resolution NMR provides spectra that consist of a number of lines and bands whose frequency, relative intensity and shape may be analysed to yield molecular parameters. The NMR parameters in questions are the nuclear shielding, σ , which describes the shielding of the nucleus from the applied magnetic field by the surrounding electrons and gives rise to chemical shifts; J , which relates to nuclear spin–spin coupling and depends upon relative nuclear orientations; and the times T_1 and T_2 which refer to the relaxation processes encountered by the nuclei excited in the NMR experiment.

Both the nuclear shielding and spin–spin coupling interactions are interpreted within the framework of quantum chemistry, whereas a quasi-classical form of mechanics is usually adopted to describe the nuclear relaxation interactions.

Nuclear Shielding (Chemical Shifts)

For an NMR experiment the basic resonance condition is given as

$$\omega = \gamma B_0 \quad [1]$$

where B_0 is the applied magnetic field in which the experiment is performed, γ is the magnetogyric ratio of the nucleus in question and ω is the angular frequency of the radiation producing the NMR transition. From this expression it follows that all nuclei with a given value of γ , e.g. protons, will produce a single absorption in the NMR spectrum. In such a situation NMR spectroscopy would not be of much chemical interest. In reality the expression for the resonance condition needs to be modified to include the fact that the value of the magnetic field experienced by the resonating nuclei is usually less than B_0 owing to shielding of the nucleus in a molecule by the surrounding electrons. Thus the expression for the resonance condition becomes

$$\omega = \gamma B_0(1 - \sigma) \quad [2]$$

where σ is the nuclear shielding. In NMR experiments the resonance frequencies are normally reported relative to that of a given nucleus in a standard molecule added to the experimental sample as a reference. The shielding difference, or chemical shift δ , is then defined as the difference in shielding between the given nucleus in the reference compound, σ_{ref} , and that of the nucleus of interest, σ_{sample} . Namely

$$\delta = \sigma_{\text{ref}} - \sigma_{\text{sample}}$$

From which it follows that a shift of resonance to high frequency, denoted by an increase in δ , corresponds to a decrease in σ_{sample} .

In seeking a molecular interpretation for σ it is important to realize that the nuclear shielding is represented by a second-rank tensor. Many NMR experiments are performed on nonviscous solutions, or sometimes on

gaseous samples, in which case rapid, and random, molecular motion ensures that the nuclear shielding experienced is the scalar corresponding to one-third of the trace of the tensor.

NMR measurements taken on solid and liquid crystal phases can yield values for the individual components of the shielding tensor and its anisotropy, $\Delta\sigma$. For linear and symmetric-top molecules,

$$\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp} \quad [3]$$

where $\sigma_{\parallel}$ refers to the shielding component along the major molecular axis and $\sigma_{\perp}$ is that in the direction perpendicular to it. For less symmetrical molecules,

$$\Delta\sigma = \sigma_{xx} - \frac{1}{2}(\sigma_{\beta\beta} + \sigma_{\gamma\gamma}) \quad [4]$$

where the σ_{ii} are the principal tensor components taken in accordance with the convention $\sigma_{xx} > \sigma_{\beta\beta} > \sigma_{\gamma\gamma}$.

The first report on the theory of nuclear shielding appeared in 1950; since then many reports have appeared of attempts to calculate shieldings, most of them within the framework of molecular orbital (MO) theory. Some of the earlier results, particularly those based upon semi-empirical MO methods, are at best indicative of shielding trends in series of closely related molecules. In general these are unsuitable for predictive purposes. In recent years this situation has changed dramatically and *ab initio* MO calculations of nuclear shielding are routinely providing satisfactory results. In principle, quantum chemistry can provide a full account of all molecular properties. In practice, various approximations are introduced into the calculations to make them tractable. Such approximations tend to produce limitations on the results obtained from the calculations. For example, calculations at the Hartree–Fock (HF) level involve a single determinant for a rigid isolated molecule; consequently, the effects of electron correlation, variations in geometry and media influences on nuclear shielding are ignored. Normally such effects are considered separately as are possible relativistic effects on the shielding of heavier nuclei. Calculations of molecular magnetic properties, such as nuclear shielding, can suffer from all of these limitations and an additional one known as the gauge problem. This arises from the use of perturbation theory to describe the rather small contribution to the total electronic energy of the molecule provided by the applied magnetic field in the NMR experiment. The magnetic perturbation is described by the orbital angular momentum operator. Since this operator is not invariant with respect to translations, its influence depends upon the position at which it is evaluated. Consequently, the result obtained for the calculated nuclear shielding depends upon the choice of origin for the calculation. This theoretical artefact has to be dealt with

before comparison takes place between experimental and theoretical shielding data.

One way to combat the gauge problem in nuclear shielding calculations is to employ large basis sets in calculations using the coupled Hartree–Fock (CHF) approach. If smaller basis sets are employed, the shielding results obtained are gauge-dependent unless the gauge origin is taken to be at the nucleus in question; these are referred to as common-origin calculations. An example of ^{13}C nuclear shielding calculations of this type is provided by buckminsterfullerene, C_{60} : all of the carbon atoms are equivalent in this molecule and thus symmetry arguments can be used to reduce the number of integrals to be evaluated. If a relatively modest basis set, such as 6-13G*, is used in the calculation of the nuclear shielding, then calculations become very time consuming and unproductive. Consequently, it seems unlikely that common-origin nuclear shielding calculations will become widely affordable.

An alternative to using large basis sets to overcome the gauge problem is to introduce gauge factors either into the atomic orbitals of the basis set or into the MOs of a CHF calculations of nuclear shielding. The inclusion of gauge factors in the atomic orbitals used gives rise to the gauge-included atomic orbital (GIAO) method. In contrast the IGLO (individual gauges for localized orbitals) method employs individual gauge origins for different localized molecular orbitals. Both the GIAO and IGLO methods are referred to as local origin variants of the CHF method.

An alternative to the CHF calculations of second-order magnetic properties is to use the random-phase approximation within the equations of motion procedure. This has developed into a method using localized MOs with local origins (LORG). The LORG method results in a localization of the MOs used and provides a pathway to the decomposition of the calculated nuclear shielding into individual local bond and bond–bond contributions. Thus the LORG and IGLO methods of calculating nuclear shieldings are analogous to each other. The results of some ^{13}C shieldings and their anisotropies, produced by IGLO, LORG and GIAO calculations, are given in **Table 1**.

The results given are obtained by the use of medium-sized basis sets; e.g. sets of triple zeta quality with a set of d polarization functions for the heavy atoms. In general, the calculated and experimental results are in satisfactory agreement. In comparing the relative merits of the GIAO, IGLO and LORG methods, it appears that the GIAO procedure is the more efficient in terms of the convergence of the shielding value with respect to the size of basis set used. However, the IGLO and LORG calculations produce shielding contributions that may be attributed to specific molecular regions. Since the GIAO, IGLO and LORG calculations can all be performed with different levels of basis set quality, the results obtained

are found to be dependent upon the choice of basis set. An example of the dependence of ^{13}C shieldings calculated by the GIAO method upon the choice of geometry and basis set is provided in Table 2.

Table 1 Comparison of some ^{13}C shieldings and their anisotropies $\Delta\sigma$ (in ppm) produced by IGLO and GIAO calculations and experimental values

Molecule and $\Delta\sigma$	IGLO	LORG	GIAO	Experimental
CH_4	196.7	196.0	193.0	195.1
HCN	72.9	77.3	74.8	82.1
$\Delta\sigma$	306	301	304.8	316.3 ± 1.2
C_2H_2	116.4	122.3	118.3	117.2
$\Delta\sigma$	243.3	235.0	241.0	240 ± 5
CO	-6.0	-	-21.3	1.0
$\Delta\sigma$	420.0	-	439.0	405.5 ± 1.4
C_2H_6	183.5	184.7	181.2	180.0
$\Delta\sigma$	13.5	8.0	11.3	-
CH_3OH	157.2	145.7	134.6	136.6
$\Delta\sigma$	-	60.5	77.3	63.0
H_2CO	-3.8	4.0	2.6	-8.0
$\Delta\sigma$	183.8	183.0	196.5	-

The use of experimental geometries is indicated by NOOPT (none optimized geometry); also included are optimized geometries from *ab initio* MO calculations using 4-31G and 4-31G** basis sets, whereas the ^{13}C shieldings are calculated with 3-21G, 4-31G and 4-31G** basis sets. The best agreement with the experimental shieldings is given by the calculations using experimental molecular geometries and the 4-31G** basis set; in this case the average least-squares error for the set of molecules studied is 2.7 ppm.

In general, GIAO, LORG and IGLO calculations are capable of producing shieldings for nuclei from the first and second long rows of the periodic table to within about 3 or 4% of an element's shielding range. Thus these calculations can be used for predictive purposes as well as providing some information on the molecular electronic factors that determine the extent of nuclear shielding and its variations.

Another method of tackling the gauge problem in nuclear shielding calculations is to employ individual gauges for atoms in molecules (IGAIM). This procedure differs from the GIAO, IGLO and LORG procedures in

Table 2 Calculated and observed isotropic ^{13}C chemical shifts (in ppm from CH_4) of the resonant nuclei (*C) using NOOPT/4-31G, 4-31G/4-31G, NOOPT/3-21G, NOOPT/4-31G** and 4-31G**/4-31G** basis sets

Molecule	NOOPT/4-31G	4-31G/4-31G	NOOPT/3-21G	NOOPT/4-31G**	4-31G**/4-31G**	Experimental

that the gauge origins in IGAIM are determined by properties of the charge density in real space rather than by the behaviour of the chosen basis functions in the Hilbert space of the molecular wavefunction. The results of some IGAIM ^{13}C shielding calculations are given in **Table 3**, where they are compared with the results obtained from conventional CHF calculations using the same basis set.

In the CHF calculations, the common gauge origin is placed at the nucleus whose shielding is being deduced. **Table 3** shows that the IGAIM results are in much better agreement with experiment than those produced by the CHF calculations. The absence of electron correlation effects from HF calculations is most noticeable in cases of 'electron-rich' molecules containing, for example, multiple bonding and lone pair electrons. It is possible to enhance the local origin methods for calculating nuclear shieldings by including some electron correlation effects. The GIAO method has been extended by means of many-body perturbation theory (MBPT). The results of some GIAO and GIAO-MBPT calculations of ^{17}O shieldings are compared in **Table 4**, where the effect of including electron correlation is seen to lead to an increase in the calculated values of the shieldings. This increase usually results in a closer agreement between the calculated and experimental shieldings.

Electron correlation effects have been included in the IGLO method by means of a nonperturbative multi-configuration extension to give the MC-IGLO method. **Table 5** shows the results of some MC-IGLO calculations of ^1H , ^{13}C , ^{17}O , ^{19}F and ^{31}P nuclear shieldings in comparison with comparable results from experiment and from the self-consistent fixed (SCF)-IGLO method.

Table 3 Comparison of absolute ^{13}C shieldings (in ppm) calculated by the IGAIM method and the CHF procedure, using the same 6-31 G** (2d, 2p) basis set, with experimental values taken as thermal averages at 300 K in the limit of zero gas density

The effects of electron correlation on the calculated nuclear shieldings are shown to be small for methane and phosphine but much more significant for fluorine, carbon monoxide and ozone, which are 'electron rich' molecules. For the central oxygen atom of ozone, the effect of including electron correlation in the shielding calculations is to produce an increase by over 2000 ppm.

The LORG method of calculating nuclear shieldings has been combined with the second-order polarization propagator (SOPPA) technique to produce the second-order LORG or SOLO procedure. The results of some LORG and SOLO ^{15}N shielding calculations are compared with experiment and with some IGLO results in **Table 6**.

The conjugated heterocycles chosen for the study represent cases where electron correlation effects are predicted to be significant. In general, the inclusion of electron correlation leads to an increase in the calculated nitrogen shieldings and usually to an improved agreement with the experimental results. A comparison of the LORG and SOLO data given in **Table 6** shows root mean square errors of 49.2 and 19.9 ppm, respectively.

Density functional theory (DFT) is an alternative to HF methods for describing molecular electronic structure. Electron correlation effects are explicitly included in DFT calculations. Coupled DFT (CDFT), together with the IGLO method, has been used in some nuclear shielding calculations and some results for ^{13}C , ^{15}N , ^{17}O , ^{19}F and ^{31}P are shown in **Table 7**. For comparison

purposes, the results of some GIAO calculations, not including electron correlation, and experimental results are given. The CDFT results are seen to be in much better agreement with experiment than are those from the GIAO calculations.

Spin-Spin Couplings

Many NMR signals appear as multiplets, the structure of which arises from spin-spin coupling interactions with other nuclei in the molecule. The separation between adjacent members of a multiplet can give the value of J , the spin-spin coupling interaction between the spin coupled nuclei. For nuclei whose spin is $\frac{1}{2}$, the relative signal intensities of the members of a given first-order multiplet are given by the factors of a binomial expansion. If A and B are the two spin- $\frac{1}{2}$ coupled nuclei then the NMR signal for A will consist of a multiplet with $n + 1$ lines due to spin-spin coupling to n equivalent B nuclei, provided the chemical shift between A and B is large relative to J_{AB} .

As for σ , the value of J depends upon the chemical environment of the nuclei concerned. Hence values of J are of use in molecular structure determinations. Unlike the case for nuclear shieldings, values of J are independent of the magnitude of the applied magnetic field used in the NMR experiment; thus the gauge problem does not arise when considering quantum-chemical calculations of J . Nuclear spin-spin couplings arise from indirect interactions between the spin, I , of neighbouring nuclei. The spin orientation information is transmitted from one nucleus to the other by means of both bonding and nonbonding electrons encountered on the spin coupling pathway.

Values of J are usually given in Hz as is apparent from the following definition of the energy, E_{AB} , of the coupling interaction between nuclei A and B:

$$E_{AB} = hJ_{AB}I_AI_B \quad [5]$$

As in the case of nuclear shielding, J_{AB} is a scalar quantity; an estimate of the anisotropy of the corresponding second-rank tensor may be forthcoming from measurements on oriented samples. The theoretical aspects of spin-spin coupling are based upon three types of electron-coupled interactions between the electrons and nuclei of the molecule concerned. Normally the largest of these is the contact (C) interaction between the electron and nuclear spins; the second one is a magnetic dipolar (D) interaction between the electron and nuclear spins; finally there is the orbital (O) interaction between the magnetic field produced by the orbital motion of the electrons and the nuclear magnetic dipole.

Accurate calculations of spin-spin couplings provide a challenge to the theoretician. Reliable results are difficult to obtain for molecules of chemical interest, because spin-spin couplings rely upon subtle aspects of molecular electronic structure. Consequently, a deeper understanding of the relationships between spin-spin couplings and molecular structure could considerably enhance the application of high-resolution NMR spectroscopy to the elucidation of molecular electronic structure. At present the theoretical analysis of spin-spin couplings is advancing in two different directions. For small molecules with light atoms, i.e. those up to the second row, highly accurate *ab initio* MO calculations are being applied. Alternatively, rather simple semiempirical calculations are used to provide some understanding of possible relationships between physical phenomena and experimental data.

At the HF level, the C contribution to spin-spin couplings is most difficult to evaluate accurately owing to the poor description provided of the electron spin densities at the coupled nuclei. Consequently, it becomes necessary to include electron correlation effects to provide accurate calculations of spin-spin couplings. Many-body perturbation theory can be used to introduce some electron correlation into calculations of the C

contribution to spin–spin couplings. Using this approach for some first-row hydrides, where the C contribution is expected to dominate, satisfactory agreement is found between calculated and observed values of one-bond couplings. However, the calculated values of $^2J(\text{H–H})$ are much too large, which suggests that electron correlation effects beyond second order are important in determining the magnitudes of spin–spin couplings.

The use of multiconfiguration linear response (MCLR) theory is another approach to the calculation of spin–spin coupling interactions. As is usual for *ab initio* MO calculations, the results obtained are found to be basis set dependent. In general, satisfactory agreement with the available experimental data is achieved.

Other *ab initio* MO calculations of spin–spin couplings include those based upon polarization propagator methods, e.g. RPA, SOPPA and the coupled cluster single and double polarization propagator approximation (CCSDPPA). These three methods have been used to calculate the C contributions to the values of $^1J(\text{C–H})$ and $^2J(\text{H–H})$ for methane as functions of bond length variation in the region of the equilibrium geometry, as shown in Figures 1 and 2, where S_1 represents the symmetric stretching coordinate. In the case of the CCSDPPA result, about 91% of the correlation contribution to the value of $^1J(\text{C–H})$ is recovered, whereas the corresponding figure for the SOPPA calculation is about 79%. For the calculations on $^2J(\text{H–H})$, the corresponding recoveries are 88% and 79% for the CCSDPPA and SOPPA methods, respectively.

Semiempirical MO calculations of spin–spin couplings are often used in conjunction with conformational analysis studies. In general, the investigations are based upon a dihedral angle dependence of the $^3J(^{13}\text{C–}^1\text{H})$ values. However, calculations of longer-range couplings can also play a role in understanding molecular structure.

Self-consistent perturbation theory (SCPT) semi-empirical calculations have been used in a study of the effects of the oxygen lone pair electrons on $^1J(\text{C–C})$ values in furan derivatives. The results show that the effects of the lone pairs on the spin–spin couplings, and the changes due to protonation, are similar to those resulting from the lone pair electrons on the nitrogen atom in imines.

Nuclear Spin Relaxation

The time taken for nuclear spin relaxation to occur constitutes the third type of chemically interesting NMR parameter. Since NMR is normally observed in the radiofrequency region of the electromagnetic spectrum it involves rather low-energy transitions; consequently spontaneous emission tends to be of negligible importance for NMR relaxation. Nuclear spin relaxation may be characterized by two relaxation times, T_1 and T_2 . The

Figure 1 Dependence of the contact contribution to $^1J(\text{C–H})$ on the symmetric stretching coordinate S_1 of methane. Results are given at the RPA, SOPPA and CCSDPPA levels of theory.

Figure 2 Dependence of the contact contribution of $^2J(\text{H–H})$ on the symmetric stretching coordinate S_1 of methane. Results are given at the RPA, SOPPA and CCSDPPA levels of theory.

spin–lattice relaxation time, T_1 , relates to the exchange of nuclear magnetization in a direction parallel to that of the applied magnetic field. T_2 , the spin–spin relaxation time, applies to the exchange of magnetization in

directions perpendicular to that of the applied magnetic field.

The ideal NMR line shape is Lorentzian and its full width at half-height, $W_{1/2}$, is controlled by T_2 :

$$W_{1/2} = \frac{1}{\pi T_2} \quad [6]$$

For nonviscous liquids, T_1 and T_2 are usually equal; thus comments made about T_1 apply equally to T_2 .

A number of mechanisms may contribute to nuclear spin relaxation times. These mechanisms operate in chemically distinct ways so that the identification of which particular mechanism(s) is operative can be of chemical interest. For any mechanism to be operative in producing spin relaxation it must produce an oscillating magnetic field at the nuclear site. The frequency of this local magnetic field must be equal to the resonance frequency of the nucleus to be relaxed. If this situation occurs, then a relaxation transition may be induced.

The microdynamic behaviour of molecules in fluids is attributed to Brownian motion, and the frequency distribution of the components of the local fluctuating magnetic field is expressed by a power spectral density. The component of this spectral density at the resonance frequency is responsible for nuclear relaxation. The magnitude of this component, taken together with the energy of interaction between the nuclear spin system and the molecular motions, determines the value of T_1 .

In discussing nuclear relaxation phenomena it is normally assumed that the motional narrowing limit applies:

$$\omega_0^2 \tau_0^2 \ll 1$$

where ω_0 refers to the resonance frequency and τ_0 is the correlation time characterizing the appropriate molecular motion. For the motional narrowing limit to apply, the molecules in question must be tumbling rapidly; this implies small molecules in a low-viscosity medium and a relatively high temperature. As shown in **Figure 3**, under these conditions T_1 becomes frequency independent and equal to T_2 . Larger molecules may not satisfy the motional narrowing limit, for example macromolecules, in which case T_1 and T_2 are almost certain to be unequal and to have different frequency dependences.

Provided the extreme narrowing conditions are satisfied, then the left-hand side of **Figure 3** is the appropriate one for further discussion of the various mechanisms that contribute to T_1 .

Nuclear magnetic dipole relaxation interactions may occur with other nuclei, or with unpaired electrons. These processes usually dominate the relaxation of spin- $\frac{1}{2}$ nuclei. Both intra- and intermolecular interactions may contribute to dipole-dipole nuclear relaxation times. The value of T_1 due to the intramolecular dipole-dipole

Figure 3 Schematic representation of the nuclear relaxation times T_1 and T_2 as functions of the correlation time τ_0 .

process is proportional to the sixth power of the internuclear separation. Consequently, this process becomes rather inefficient in the absence of directly bonded magnetic nuclei. However, it follows that a measurement of T_1 can provide an estimate of internuclear separation that can be of chemical interest. The nuclear Overhauser effect (NOE) depends upon the occurrence of dipole-dipole relaxation processes and can similarly provide an estimate of internuclear separation.

The large magnetogyric ratio of the proton coupled with its common molecular occurrence ensures that dipole-dipole interactions with protons frequently dominate the relaxation of other spin- $\frac{1}{2}$ nuclei such as ^{13}C and ^{15}N .

The electron has a magnetogyric ratio that is more than 600 times larger than that of the proton; thus, if unpaired electrons are present, their dipole-dipole interaction with a given nucleus normally controls the relaxation of that nucleus. Consequently, paramagnetic centres may be introduced to override nuclear-nuclear relaxation processes in certain cases, for example to reduce embarrassingly long relaxation times and to remove NOEs in cases where they are not required.

Nuclei with a spin $I > \frac{1}{2}$ have electric quadrupole moments in addition to the magnetic dipole moments required for the NMR experiment. The quadrupole moment may interact with a local electric field gradient to provide a very efficient nuclear relaxation process, and thus broad NMR signals. The value of T_1 for the quadrupolar relaxation process depends critically upon the electronic environment of the nucleus in question. This is demonstrated by the NMR line widths of about 10 Hz for ^{35}Cl in NaCl and about 10 kHz for ^{35}Cl in CCl_4 . In the former example, the electronic environment of the chloride ion is approximately spherical; thus there is only a small field gradient, at best, at the site of the chlorine and the line width is controlled by the less efficient

dipole–dipole process. For covalently bonded CCl_4 , the large field gradients at the chlorine nuclei give rise to rapid quadrupolar relaxation.

Spin–rotation interactions may also produce nuclear relaxation. These arise from interactions between nuclear magnetic moments and rotational magnetic moments of the molecules containing the nuclei in question. A direct transfer occurs of nuclear spin energy to the molecular motion. This contrasts with the dipole–dipole and quadrupole mechanisms, which operate via an indirect energy transfer. The value of T_1 due to spin–rotation interactions decreases as the temperature increases, which is in contrast to the other nuclear relaxation mechanisms. Hence the observed temperature dependence of T_1 may be used to demonstrate the contribution or absence of spin–rotation interaction processes to the nuclear relaxation. Spin–rotation relaxation is most likely to be dominant for small molecules tumbling rapidly at high temperatures. Thus it is likely to be of particular importance for vapour-phase studies.

Anisotropy of the nuclear shielding tensor may also contribute to nuclear relaxation. Brownian motion can modulate the nuclear shielding tensor and thus provide a fluctuating magnetic field. The corresponding relaxation times depend inversely upon the square of the applied magnetic field and the square of the shielding anisotropy. Thus this relaxation process is likely to be of most importance at very high magnetic field strengths and for heavier nuclei, which tend to have very large shielding anisotropies, e.g. ^{195}Pt and ^{199}Hg . The fact that T_1 values for this process depend upon the strength of the applied magnetic field provides a means of determining the contribution or absence of nuclear shielding anisotropy to the relaxation of a given nucleus.

If chemical exchange or internal rotation causes the spin–spin coupling interaction between two nuclei to

become time dependent, then scalar relaxation of the first kind can occur. Scalar relaxation of the second kind relates to the case where the relaxation rate of a coupled nucleus is fast compared with $2\pi J$. Coupling to a quadrupolar nucleus can give rise to this relaxation mechanism. For scalar coupling relaxation to be operative, it is generally important that the resonance frequencies of the coupled nuclei be similar. This is, perhaps, the least common of the nuclear spin relaxation processes considered.

Introduction

The detection and measurement of scattering from particles is a key analysis tool across many different industries. Different types of scattering methods, which rely on the use of many different types of incident radiation including visible/UV light, microwaves, near-IR, X-rays and neutrons, allow the analysis of material defects and particles across a wide size range (angstroms to microns). Of the types of incident radiation listed above, the scattering of visible light is the most widely used as a non-invasive analysis tool. For the purposes of this article, only laser light scattering will be discussed along with its applications. This form of electromagnetic scattering can be either elastic, where there is no change in energy between the incident and scattered light, or inelastic, where a change in energy occurs. Rayleigh scattering and the more general Mie solution are the two best known theories for elastic scattering. These scattering theories form the basis of a number of light scattering methods and applications that will be discussed further in this article. Inelastic scattering, such as Raman scattering, is discussed elsewhere in this encyclopedia and will not be covered here.

The advent of the laser enabled rapid advances to be made in the field of light scattering as the use of a coherent, monochromatic beam of light greatly improved the quality and sensitivity of the measurements. The use of light scattering for the characterization of polymers was initially the most prevalent application area.

However, the expansion of methodologies and applications has continued, and forms of light scattering, extending from light detection and ranging (LIDAR) to dynamic light scattering (DLS), are now used in many different industrial sectors including atmospheric analysis in meteorology, powder analysis in cosmetics, and drug substance analysis in the biopharmaceutical industry.

This article describes a number of applications of light scattering, where the technique plays an important analytical role. In particular, the focus will be on the application of DLS and Doppler velocimetry light scattering (electrophoretic light scattering) to the characterization of nanoparticles and biotherapeutic drugs. Emphasis will be placed on the analysis of light scattering data and the importance of certain measurement parameters as well as sample preparation methods and their impact on the data quality.

Elastic Light Scattering Theory

Electromagnetic scattering, and in particular the scattering of electromagnetic waves in the visible range (light scattering), is an understood phenomenon with well-established theories. The two most widely used theories for the explanation of elastic light scattering are Rayleigh scattering and Mie scattering.

Rayleigh Scattering

Lord Rayleigh provided the first quantitative theoretical treatment of light scattering for small, spherical, homogeneous particles, which is now known as Rayleigh theory. The theory applies to spherical particles whose size is much smaller than the wavelength of light being used. Typically this means that the particle diameter has to be less than one-tenth of the wavelength of the incident light. When light waves hit a particle, they cause a distortion in the molecular electronic distribution inducing an oscillating dipole, which will irradiate (scatter) in all directions. The size of this dipole governs the intensity of the scattered light and is dependent on the polarizability of the particle, while the angular dependence of the intensity provides information on the size and shape of the particle. The polarizability of a particle is linked to its molecular weight. For this reason, Rayleigh scattering, or classical light scattering, can be used to obtain the molecular weight of particles so long as the particle

concentration and specific refractive index (RI) increment (dn/dC) are known.

Mie Scattering

In 1908 Gustav Mie developed a theory to explain the scattering of radiation by homogeneous, spherical particles at all particle diameter-to-wavelength ratios. Mie's complete solution to Maxwell's electromagnetic field equations has become important to a number of application areas, notably in the field of meteorology where the sizes of the scattering particles found in clouds are similar or larger than the wavelength of the incident light. The theory has also found use in the imaging of substances such as milk and biological tissue. The theory uses a number of assumptions, namely that the particles being measured are spherical, the scattered light is measured from a single scattering event, the optical properties (absorbance and RI) of both the particle and dispersant are known, and the particles are homogeneous. Despite Mie theory being developed at the turn of the twentieth century, and updated formulations being developed in the 1940s, only recently has modern computing power allowed the theory to be applied to light scattering experiments such as laser diffraction measurements over a large dynamic range of particles sizes. Earlier instruments used the Fraunhofer approximation to estimate particle sizes. However, while simpler to use than the Mie theory, the Fraunhofer approximation model can lead to significant errors in the estimation of the particle size fraction for particles less than 50 μm in diameter. These errors become particularly critical when the particles are transparent. The Fraunhofer approximation makes a number of assumptions above and beyond those used in Mie theory that only hold for the scattering of light by large particles. This is why modern laser diffraction instruments, which are required to measure particles ranging in size from 2000 to 0.02 μm , use Mie theory to inversely model the observed scattering intensities.

Overview of Methods and Applications

Environmental Applications

Atmospheric measurements

The light scattering technique known as LIDAR is well established as a means of measuring atmospheric composition, cloud formations, and aerosols for both meteorological and military reasons. The method works in a similar way to radar but uses much shorter wavelength radiation, such as visible light, which scatters more strongly from rain droplets and aerosols. By using high-powered pulse lasers, remote sensing of the backscatter signal from aerosols can be carried out to determine distance profiles. An adaptation of LIDAR, where two

lasers with different wavelengths known as the online and offline wavelengths are used, is known as differential absorption LIDAR (DIAL). The online wavelength is tuned so that it is absorbed by a gas of interest, while the offline wavelength is not absorbed. Measurement of the difference in absorbance between the two wavelengths allows range-resolved concentration measurements to be made of a number of atmospheric constituents, such as water vapor and ozone. All of these measurements rely on modeling using Mie theory and a good knowledge of the optical properties of these atmospheric components.

Laser Doppler velocimetry, which will be discussed below in more detail in the context of zeta potential measurements of proteins and nanoparticles, has been used alongside LIDAR to measure the speed of global winds. Doppler LIDAR, as the technique is known, uses the frequency shift of the backscattered light to estimate the speed at which atmospheric particles are travelling and, hence, the velocity of the air. This application of light scattering is currently being used to help the renewable energy sector with the positioning of wind farms by analyzing certain characteristics of the wind patterns in locations of interest.

Water analysis

The water industry uses light scattering techniques for a number of important measurements of water effluent and sewage sludge flocculation. Traditionally, water treatment plants monitor the quality of water that is released into the public distribution system by either using turbidimetry (nephelometry) or more recently particle counters. The former technique is more established and relies on the measurement of scattered light from the water. This is a simple, qualitative measurement that requires the user to calibrate the instrument using standards that are traceable to the primary standard formazin. Samples are usually illuminated using a broad-spectrum tungsten lamp. The scattered light, in the wavelength range 400–600 nm, is detected at a 90° angle, while the intensity of the remaining light is detected in the forward direction. The ratio of the light intensities at the two detectors allows the turbidity to be calculated. Measurements are reported as either nephelometric turbidity units (NTU) or more correctly as formazin nephelometric units (FNU).

Focused beam reflectance measurement technology (FBRM) is another light scattering technique that is commonly used in the sewage treatment industry. The technique allows real-time, in-process measurement of highly turbid samples. The technique uses an inline probe containing a laser that is focused to a point at the surface of the probe window, which is in contact with the process sample. The focused beam is rotated in a circular path at a controlled scan speed, and pulses of backscattered light are detected by the probe as the focused beam passes over particles and

agglomerates. The length of these pulses correlate to the distance across each particle and, by multiplying the length of each pulse by the scan speed, the distance across each particle (chord length) can be calculated. High numbers of chord lengths are measured each second, which enable changes in the particle size distribution and particle count to be monitored. An example where this technique has been used is the analysis of cationic polyelectrolyte-induced flocculation of sewage sludge. The technique proved very useful for the choice and concentration optimization of the polyelectrolyte flocculant.

Industrial Applications

Light scattering is used in a number of industrial processes to analyze particle size distribution and ensure that quality control measures are met. A number of different light scattering techniques and methods are used across these application areas, such as laser diffraction, diffusing wave spectroscopy (DWS), static light scattering (SLS), nephelometry, DLS, and FBRM technology.

Cosmetics industry

The cosmetics industry uses light scattering to analyse the size distribution of particles and emulsions in many of its products such as facial powders, moisturizers, and lipsticks.

The selective absorptive and reflective properties of the pigments used in lipsticks, for instance, are intrinsically linked to the size of the pigments. The ability to absorb light, known as the tinctorial strength, increases with decreasing particle size, while gloss is governed by the fraction of material greater than 1 μm in size. The use of laser diffraction, at the milling stage of production, enables rapid analysis of the milling process across a wide size range of both powders and dispersions. Moisturizers are essentially oil-in-water emulsions and their stability depends, critically, on the size distribution of the oil droplets and their zeta potential. Depending on the size of these droplets, DLS can be used to measure the size distribution, while electrophoretic light scattering can be used to measure the zeta potential.

Cement industry

By far and away the most popular technique within the cement industry to measure particle size distributions of dispersed cement powders is laser diffraction (low-angle laser light scattering). The cement industry uses light scattering to ensure consistency and predict performance of its products. Computational modeling of the hydration process requires accurate knowledge of the particle size distributions. If the particles are too fine, then cracking can occur during the curing process, while, if they are too coarse, long curing times are encountered. As with most applications of light scattering, sample preparation

(which in the case of cement means dispersion of the particles in a liquid (wet method) or aerosol form (dry method)), knowledge of the complex RI of the material and which data analysis method to use are all critical to obtaining the correct particle size distribution. The two data analysis methods typically used are Mie theory and Fraunhofer approximation. As discussed earlier in this chapter, both of these approaches have disadvantages. Mie theory, however, provides a more robust data analysis method when an accurate value of the complex RI is used and the particle sizes are close to the wavelength of the incident light. Over the last few years, the industry has participated in studies to try and develop a reference material and standard method in order to improve the accuracy and precision of particle size distribution analysis. These have led to best practice guides and the development of standard sample preparation procedures for both wet and dry dispersion methods.

Food and beverage industry

Numerous products within the food and beverage industry require particle size analysis in order to ensure the consistency of the final product. Particle size is a critical characteristic as it influences stability (in the case of emulsions such as high-concentration flavor additives), mouth-feel, and flavor. A number of different techniques are used for the analysis of food colloids, ranging from rheology to ultrasonic spectroscopy and DLS. All of these techniques provide valuable information about the system they measure; however, they all require some kind of sample manipulation prior to measurement. In the late 1980s, a new light scattering method was proposed called diffusing wave spectroscopy. This new technique is similar to DLS in that it measures the time-dependent fluctuations in the intensity of scattered light and inversely relates this to the diffusion coefficient of the dispersed particles. Where this method differs from DLS is in the capability to gain information on the size of submicrometer particles at very high concentrations, where the sample is in the multiple scattering regime. DWS exploits the fact that, in the multiple scattering regime, the transport of light through the sample can be treated as diffusive. While treating the scattered light in this way, it is important to be aware that the functions that describe the correlation of the time-dependent fluctuations in the scattered intensities are dependent on the geometry of the experimental setup.

The technique is still not fully established in the food industry; however, numerous studies, of undiluted milk, have been made using DWS to measure the size of casein micelles and to investigate the process of gelation. DWS has also been used to study the effect of various polysaccharides on the properties of oil-in-water emulsions and detect structural differences at the micrometer level during destabilization experiments.

Pharmaceutical industry

Light scattering is used to monitor many processes within the pharmaceutical industry, for product development and quality control purposes, and provide non-invasive information on mean particle size, particle size distribution, molecular weight, and product stability and uniformity. These processes can include biopolymer degradation monitoring, determination of the second virial coefficient (A_2) and percentage polydispersity for crystallization screening studies, determination of protein molecular weight (native state and aggregated forms), and detection of trace amounts ($<0.01\%$ by weight) of high molecular weight (HMW) components in drug formulations.

The most widely used light scattering techniques are SLS, multi-angle light scattering (MALS), and DLS. Another technique, electrophoretic light scattering, is used for the measurement of zeta potential, which is a key physical property of any particle dispersed in a liquid environment. By measuring the zeta potential, colloid and drug product formulations can be optimized, with respect to the colloidal stability. When coupled with thermodynamic information, product stability predictions can be made.

MALS is most commonly used to obtain the molecular weight of particles such as biopolymers and proteins. As discussed in a previous section, Rayleigh theory indicates that the scattering intensity is proportional to the product of the scattering particle's molecular weight and concentration. If the particle is small (hydrodynamic diameter $\leq \lambda/10$), then Rayleigh scattering predominates and the angular dependence of the scattering intensity is minimized. When the particles are large or have extended nonspherical structures, then Mie scattering predominates and the observed scattering intensity is highly dependent on the detection angle. There is much debate, within industry and the literature, about whether single-angle versus multiple-angle detectors should be used, especially when studying small particles that can aggregate into larger species, for example, proteins. MALS is required for applications such as the measurement of HMW polymers; however, for globular proteins smaller than 500 kDa, the scattering profile is isotropic and so only a single angle measurement is required. Sizing errors can become significant when single-angle instruments are used and large aggregates, or nonspherical proteins, are studied as Mie scattering dominates. MALS has been used very successfully in conjunction with another sizing technique, size exclusion chromatography (SEC), for the absolute assignment of molecular masses. The combined technique is unsurprisingly called SEC-MALS, and the use of the light scattering detector allows correct molecular masses to be assigned to proteins that are hard to assign with SEC alone due to, for example, unwanted column-matrix interactions. SEC-MALS has also been used to characterize PEGylated

versions of therapeutic proteins to provide information on the degree of PEGylation and to detect oligomeric species that can lead to loss in product efficacy or immunogenic responses in patients.

The following sections will explore DLS and electrophoretic light scattering more thoroughly, focussing on their use for protein and nanoparticle characterization. The importance of sample preparation will be discussed alongside data analysis strategies. A description will be given of the key measurement parameters obtained from these light scattering techniques with examples of how best to use and interpret them.

Dynamic Light Scattering

The light scattered from an induced oscillating dipole will have the same frequency as the incident light but a different phase. Because the light is irradiated from different sources (particles), this difference in phases will result in constructive and destructive interferences leading to variations in the intensity. These variations, in turn, are not static due to the Brownian motion of particles. A DLS experiment measures the time-dependent fluctuations in the scattering intensity due to the particles' Brownian motion and, by analysing these fluctuations, it determines the particles' translational diffusion coefficient. Therefore, DLS is an indirect method where the hydrodynamic radius is not measured directly but rather determined from the measurement of the diffusion coefficient.

To get reliable and robust results from a DLS experiment, it is necessary to know the RI of both the dispersant and of the material, to control the temperature, and to know the viscosity of the solution. The knowledge of the RI is important because the excess of scattered light depends on the difference between the RIs of the dispersant and the material. The viscosity and the temperature, instead, affect the Brownian motion: the diffusion coefficient depends both on the temperature and on the frictional coefficient, which is related to the shape and size of the particles and to the viscosity of the solution. Therefore, errors can be introduced in the measurement by an incorrect estimation of the viscosity or by a short equilibration time. In **Figure 1** is shown the difference in hydrodynamic diameter obtained from the intensity distribution due to an incorrect estimation of the sample RI and viscosity. All three distributions refer to a single acquisition, the only difference being the values for the dispersant (RI and viscosity) fed into the program for the analysis.

The kind of solution (Rayleigh or Mie) used to analyse the scattering data depends on the size of the particles, as explained in the previous sections. For the approximation of spherical and homogeneous particles, the hydrodynamic radius (R_H) can be obtained from the Stokes–Einstein

Figure 1 Example of the effect of viscosity on the calculated hydrodynamic diameter (D_H). The distributions were obtained from the same raw data, feeding different values of RI and viscosity into the analysis program. CBS, citrate buffered saline.

equation, and it represents the radius of the hypothetical sphere that diffuses with the same speed as the particle. This assumption has to be taken into consideration when analyzing a material because the scattering signal is isotropic only when the wavelength of the incident light is much larger than the particle's dimension. With a light source such as the He-Ne laser (633 nm), the upper limit for isotropic scattering is at around 100 nm. DLS doesn't require calibration, because it is a first principle technique, but the instrument performance should be verified using latex particles according to relevant standards such as ISO13321 part 8 1996.

The Correlogram and Data Analysis Approaches (Cumulant vs. Multimodal)

The correlogram is a measure of the loss in similarity (loss of correlation) between two signals (scattered intensities) over time due to the Brownian motion of the particles. The correlation is seen to decay exponentially as a function of time, and the cumulant analysis, which is recommended by the ISO guide, fits the correlogram to a monoexponential function giving a value for the hydrodynamic radius (Z_{ave}) and a polydispersity index (PDI). The PDI is related to the width of the distribution and, therefore, is indicative of the monodispersity of the sample. In general, PDI values of 0.05 or below are from very monodisperse particles, values between 0.05 and 0.08 are indicative of samples that are nearly monodisperse, values between 0.08 and 0.7 indicate midrange polydispersity, while values above this indicate a highly polydisperse sample. It is suggested that when the PDI value is above 0.25, the Z_{ave} value should not be considered appropriate. In the cumulant analysis, the exponential function is only fitted to the first part of the correlogram, with the assumption that the sample comprises of a single family of

spherical, homogeneous scatterers, and there is no effect due to multiple scattering.

The shape of the correlogram gives an idea of the size and monodispersity of the samples and of the 'goodness' of the data. The intercept of the correlation function corresponds to the signal-to-noise ratio for the measurement; this value should lie between 0.2 and 0.8 to get good quality data. The point where the correlation function starts to decay gives an indication of the mean size of the particles in solution, while the slope is related to the polydispersity of the sample.

As an example in **Figure 2(a)** are reported three correlograms: the first one is of Tween micelles (~ 9 nm), the second and the third are of the same micelles doped with, respectively, 20 and 60 nm latex standards. From a visual inspection of the correlogram it is clear that the three samples are different, though the difference between the solution of pure micelles and the one spiked with the 20 nm particles is small. The Z_{ave} and PDI values (**Table 1**), which are obtained from the cumulant analysis, clearly indicate that only the first sample is monodisperse. It has to be noted though that when the micelles are doped with the 20 nm particles (**Table 1**), the PDI is still below 0.25 but the intensity distribution (multiexponential) is broader (**Figure 2(b)**). Therefore, though a PDI limit of 0.25 is often suggested, it is clear that PDI above 0.1 is indicative of more than one species present in solution. This data demonstrates one of the limitations of DLS: though it is very sensitive to the presence of large particles, it does not have sufficient resolution to separate the contribution of different sized particles when they differ in size below a limit of 2 to 3 times the diameter or 8 times the molecular weight.

The intensity distribution is determined using a multiexponential function (non-negative least square or CONTIN) to fit the correlation data. In this kind of

Figure 2 Correlagram (a) and size distribution by intensity and by volume (b). (a) The point where the correlation function starts to decay gives an indication of the mean size of the particles in solution. The slope is related to the polydispersity of the sample. (b) The presence of 20 nm nanoparticles in a solution of Tween micelles (~ 9 nm) determine an increase in the width of the distribution (which is related to the polydispersity of the sample), but the two peaks (micelles and 20 nm particles) cannot be resolved because the limit of DLS resolution has been reached. On the other side, the 60 nm nanoparticles peak can be resolved from the 9 nm peak of the micelles, though the values for D_H are higher than expected. From the volume distribution it is evident that the major species in solution are the Tween micelles (~ 9 nm).

Table 1 Comparison of the hydrodynamic diameters obtained for a monodisperse sample (Tween micelles) and for non-monodisperse samples (micelles spiked with 20 and 60 nm particles) using both cumulant analysis (Z_{ave} and Pdl) and multiexponential analysis (intensity and volume distributions)

Sample name	$Z_{\text{-average}}$ (d.nm)	(Pdl)	Size peak 1 intensity (d.nm)	Size peak 2 intensity (d.nm)	Size peak volume (d.nm)
Tween 20 – 0.5%	7.428	(0.074)	7.531	0	5.615
Tween 20 – 0.5% + 20 nm	8.355	(0.179)	8.721	4801	4.849
Tween 20 – 0.5% + 60 nm	47.43	(0.684)	91.28	7.531	68.06

analysis, the presence of more than one family of particle size is taken into consideration. These multiexponential algorithms, for which there is no standard and which generally vary from manufacturer to manufacturer, will generate an intensity distribution and, using the Mie theory, a distribution normalized for the volume of the scattering particles (**Figure 2(b)** – intensity and volume distribution). Going back to our example, we can notice, in the case of the micelles doped with the 60 nm particles, that the high polydispersity index (Pdl) indicates that the Z_{ave} is not a reliable size estimation of what is present in solution. In this case, the hydrodynamic diameter of the first peak from the intensity distribution gives a value closer to that of the nonspiked micelles (**Table 1**). Because the intensity of the scattered light is proportional to the square of the molecular weight, and to the sixth power of the diameter, the presence of large aggregates/particles cause a bias in the cumulant analysis: in these cases the intensity distribution will account for the presence of these other species. Moreover, if multiple peaks are present in the intensity distribution, the volume distribution will give an idea of the weight of these peaks (e.g., if the corresponding species are present only in trace amounts, the peaks will not be present in the volume distribution – see **Figure 2(b)**). When Mie theory is utilized to carry out the transformation from the intensity distribution to the volume distribution, two main assumptions are made that the particles are both spherical and homogeneous. Therefore, the volume (and number) distribution should be considered only when comparing results from measurements of the same system. The value for the hydrodynamic diameter of the main species present in solution should be taken from the intensity distribution, whenever it is not possible to use the Z_{ave} from the cumulant analysis.

Sample Preparation

In a DLS experiment it is very important to have a sample free from very large contaminants, such as dust, because their presence can affect the measured hydrodynamic radius, especially when the cumulant analysis is used (Z_{ave}). Moreover, it is advisable to acquire a minimum of three measurements for each sample to check for the solution stability. The quality of the data can be

inferred from the correlogram, and **Figure 3** shows examples of some ‘signatures’ indicative of poor sample quality. The presence of dust/large aggregates will result in a nonflat baseline in the correlogram (**Figure 3**); in these cases the sample should be filtered, whenever possible. Filtration will eliminate the dust, but care must be taken to avoid altering the equilibrium population of the oligomers/aggregates present in solution. For certain applications this filtration step is not advisable. For example, when testing the stability of protein formulations, the interest is in analysing the equilibrium population of the sample. Therefore, the measurement must be made without any pretreatment, and care should be taken in recognizing any signs of the presence of aggregates and, subsequently, in interpreting the results. In these cases, the sensitivity of DLS for large aggregates can be an advantage because these can be detected even when present at very low concentrations (<0.01% by weight).

DLS experiments need a relatively diluted solution to avoid multiple scattering events. These events occur when photons, scattered by one particle, are rescattered by other particles before reaching the detector. The rescattering increases the randomness of the signal, leading to a faster loss in signal correlation, which results in a smaller apparent size. Certain instruments detect the backscattered signal and use automatic positioning of the laser to optimize the intensity of scattered light, thereby avoiding multiple scattering events. The advantage of this optical configuration is that it is possible to measure a wider range of concentrations. In general, if a size versus concentration trend is observed, it is suggested to perform measurements at different concentrations and then extrapolate the results to infinite dilutions (i.e., zero concentration).

One of the factors affecting the diffusion of particles, and therefore the hydrodynamic radius, is the ionic strength. This physical property of the dispersant needs to be taken into consideration when comparing data from the same sample in different buffers. **Figure 4** shows the size distribution by intensity of a monoclonal antibody in H_2O and in the presence of NaCl. The presence of salt will suppress the electrical double layer, thereby increasing its translational diffusion coefficient and, as a net result, the particle will appear smaller.

Figure 3 The correlogram and the quality of the data.

Figure 4 Effect of the ionic strength on the apparent size distribution. The red data refers to a protein diluted in water; the green data refers to the same protein diluted in 200 mM NaCl.

Figure 5 reports an example of how a superficial evaluation of the data could have led to the wrong conclusion. The data relates to a protein solution, formulated at high concentration, and measured at different dilutions in its formulation buffer. The measurements were performed on different days, and by different operators (different colors in **Figure 5**). Moreover, a protein preparation was buffer-exchanged in a dispersant different from its formulation buffer. A dilution series of this preparation (pink data set in **Figure 5**) was measured to check if the buffer exchange process had caused any aggregation/oligomerization. The increase in Z_{ave} with increasing concentration, for both of the preparations, is probably due to the increase in the viscosity of the sample. If only the cumulant analysis is taken into consideration, both the buffer-exchanged sample (pink data set) and one of the

dilution series in formulation buffer (blue data set) could be considered outside specification. Comparing, instead, the hydrodynamic diameters, for each of the dilution points obtained from the intensity and volume distributions (**Figure 5**: trend in D_H obtained from the intensity and volume distributions), it is evident that the differences observed in the case of the blue data set are due to the presence of large aggregates, probably dust. The change in hydrodynamic diameter in the second buffer (pink curve) is, instead, a real effect. The presence of dust in the blue dilution series is also suggested by the higher PDI values and the shape of the correlograms. **Figure 6** shows, for simplicity, only the comparison between the correlograms and distributions obtained at 5 mg/ml for two dilution series in formulation buffer, of which one is the blue data set (the green data set in **Figure 6** corresponds to the data

Figure 5 DLS measurements of a protein at different concentrations in two different buffers performed by two operators. Yellow, black, orange, and green data sets (formulation buffer and operator 1); and pink data set (acetate buffer and operator 2). The blue data set corresponds to measurements performed after nonideal sample preparation (formulation buffer and operator 2).

Figure 6 Correlograms, intensity, and volume distributions for one dilution point in **Figure 5** (5 mg/ml). The green data refer to the 5 mg/ml data point of the blue series in **Figure 5**. The red data refer to the 5 mg/ml data point of the black series in **Figure 5**.

point at 5 mg/ml of the blue data set in **Figure 5**). From this data it is evident that the higher values of Z_{ave} for the blue set are due to the presence of a broad peak at HMW, which introduces an error in the cumulant analysis. The HMW peak can be seen in the intensity distribution, but is

not observed in the volume distribution indicating that it is present only in trace amounts.

In summary, the correlogram, the Z_{ave} , PdI, and intensity and volume distributions should all be compared to produce a meaningful interpretation of the data.

Electrophoretic Light Scattering (Laser Doppler Velocimetry)

The total potential energy of a colloidal system can be considered as the combination of two main potential energy terms: one attractive (V_a), due to van der Waals interactions, and one repulsive (V_r), due to the repulsion between the electrical double layers formed at the surface (DLVO theory). According to this theory, a colloidal system is stable when the repulsive forces overcome the attractive forces. Therefore, approaches to stabilize a colloidal system include increasing the steric repulsions (e.g., by adding a polymer layer), or increasing the repulsive forces due to the electrical double layer (e.g., using different buffer systems or counter ions). An increase in the repulsive forces can be an easy way to achieve stabilization; therefore, parameters related to the extent of surface charge can be used to predict colloidal stability.

The zeta potential is defined as the potential at the slipping plane, which is the layer of resident counter ions in the double electrical diffuse layer (**Figure 7**), and is used as an indication for the colloidal stability. The most important factor affecting the zeta potential is the pH, because it affects the surface charge and therefore the extent of the repulsion between particles. Other factors include the ionic strength, which affects the thickness of the double layer and contributes to the reduction of the particle's effective charge. Finally, the presence of additives can have similar effects on the reduction of the effective charge. In general a particulate solution is considered colloidally stable if the value of the zeta potential is above $+30\text{mV}$ or below -30mV , with values in between indicating a colloidally unstable system.

The zeta potential can be evaluated by using light scattering measurements of the Doppler shift in the frequencies of particles undergoing Brownian motion. The Doppler effect arises when an object moves relative to a source of energy. In this particular case the charged particles, moving in an electric field, will scatter the incident light with different frequency (higher) than that of the incident light (or reference beam). The magnitude of the Doppler shift, observed for the particles in an applied electric field, is related to their speed and, therefore, to their charge.

Avoiding or measuring the contribution of electro-osmosis is one of the main problems in determining the electrophoretic mobility and various manufacturers achieve this in different ways.

Zeta potential measurements should be optimized by measuring different sample concentrations and checking which one provides the best quality data. The dilutions should be carried out in the same buffer as the original material to preserve the surface charge, and attention should be paid to the conductivity of the sample because

Figure 7 Zeta potential – definition.

it can affect the results. Because the technique works on first principles, instruments do not need to be calibrated but, as for the DLS, they require verification through the use of a standard.

Conclusions

Light scattering techniques allow rapid, often real-time, noninvasive analysis of many types of materials in environments ranging from manufacturing plants to field-based measurements from aircraft. For this reason a large number of methods and applications have been developed. Robust theories exist, which enable data to be analyzed and interpreted. However, these theories rely on key assumptions, which must be understood in the context of the measurement and material being analyzed, otherwise the quality of the results will be questionable. When analyzed correctly, data from light scattering measurements can provide information on the average particle size, particle size distribution, polydispersity, molecular weight, and sometimes information on the particle shape. These physical characteristics govern many of the properties of particles and their colloidal suspensions. Critically, this information can be gained noninvasively, meaning sensitive or complex systems can be analyzed without unnecessary manipulation. That said, for certain light scattering techniques such as DLS, MALS, and electrophoretic light scattering, sample preparation is extremely important and the material's and dispersant's optical properties must be known while other key physical properties of the sample must be controlled during the measurement.

Peptides and Proteins Studied Using Mass Spectrometry

Michael A Baldwin, University of California, San Francisco, CA, USA

This article is reproduced from the previous edition, volume 3, pp 1753–1763, © 1999, Elsevier Ltd.

In the 1960s it was impossible to ionize and analyse even a small peptide by mass spectrometry unless it was first made volatile by derivatization, such as acetylation and/or permethylation. Since then, 'soft ionization' methods have made mass spectrometric analysis of peptides and proteins a routine activity. Such methods employed for ionization and analysis of peptides and proteins have included field desorption (FD) from a heated emitter by high electric fields, direct chemical ionization (DCI) by the interaction of a hot plasma with a solid sample, fast atom bombardment (FAB) involving bombardment of an analyte solution with high energy xenon atoms or caesium ions, plasma desorption (PD) using nuclear fission fragment bombardment of a sample on a solid support such as nitrocellulose, electrospray ionization (ESI) by evaporation of charged droplets of analyte solution, and matrix-assisted laser desorption/ionization (MALDI) by laser irradiation of crystals of a matrix doped with analyte. Several of these have found limited use but the almost universal utility of ESI and MALDI for the analysis of macromolecules of virtually unlimited mass range with extreme sensitivity has caused these two methods to supplant all other techniques, so only these methods will be discussed further.

At its simplest level, MS measures molecular masses. With calibration it can also determine quantities on a relative or absolute scale for 'pure' compounds and, with varying degrees of success, for components in a mixture. The analysis of complex mixtures such as a protein digest may require coupling with a separative method such as chromatography (GC-MS or LC-MS) or electrophoresis, either off-line (SDS-PAGE) or on-line (CE-MS). Further experiments can provide detailed structural information, e.g. peptides can be sequenced by collision-induced dissociation (CID) of their molecular ions and tandem MS (MS/MS). MS may also be used in conjunction with chemical modification or enzymatic digestion of a protein to aid its identification and/or sequence analysis. In practice, the diverse techniques available for ionization and mass analysis allow experiments to be optimized to answer very specific questions.

Mass Spectrometry

Sample Preparation and Ionization Methods

Optimization of sample preparation depends upon the nature of the sample, the information required and the

type of mass spectrometer available. It is desirable to minimize salts and detergents, and if buffers are unavoidable, these should be volatile whenever possible, e.g. ammonium formate or ammonium bicarbonate. In general MALDI is more tolerant of impurities than ESI. It may be essential to remove salts and detergents by dialysis, precipitation, absorption/elution from beads or a membrane, or absorption onto a small column and elution into the mass spectrometer. Achieving such separations without substantial losses is frequently complicated by limited amounts of material, sample aggregation, hydrophobicity and binding to surfaces.

Most peptides and proteins contain readily protonated basic sites, suitable for positive ion MS. Analytes are ionized directly from liquid solution for ESI but from the solid state for MALDI: consequently sample handling is fundamentally different for these alternative methods. In ESI-MS, liquid is usually introduced in a continuous stream, ideal for direct coupling with reversed phase high performance liquid chromatography (RP-HPLC), which is applicable to the separation of most peptide mixtures and many proteins. However, trifluoroacetic acid (TFA), widely used to optimize separations by RP-HPLC, can inhibit ionization in ESI-MS. Solvent systems developed for LC-MS replace TFA by formic acid; alternatively low flow rates from capillary HPLC columns can be supplemented with solvents more compatible with ESI-MS. An alternative to an externally pumped system is provided by nanospray, in which a small quantity of sample solution is placed in a capillary tube drawn to a fine tip. Liquid flows out at $\sim 20\text{--}50\text{ nL min}^{-1}$ under the combined influence of capillary action and an applied electric field, allowing each sample to be studied for an hour or more, which assists studies on mixtures such as protein digests. Fortunately, peak intensity in ESI or nanospray is largely independent of flow rate; consequently low flow rates efficiently conserve samples that are difficult to isolate and purify.

For MALDI-MS the analyte as a pure compound or a mixture is co-crystallized with a matrix that absorbs laser radiation and promotes ionization. Matrix materials ideal for peptides and proteins are aromatic acids such as sinapinic acid, 2,4-dihydroxybenzoic acid, and α -cyano-4-hydroxycinnamic acid, each having slightly different ionization characteristics. Published protocols for optimization of sample preparation try to achieve multiple,

evenly distributed, small crystals. It is often necessary to remove salts by washing the crystals with water after they have been deposited.

Measurement of Molecular Mass

MS separates ions according to mass/charge (m/z). Peptides and proteins ionized by ESI under acidic conditions acquire multiple charges, z being roughly proportional to m , with m/z in the range 500–1500. In practice a distribution of charges gives multiple peaks in the mass spectrum, the spacing of which allows z to be calculated. The raw data for a pure compound can be deconvoluted to a zero-charge profile of the molecular mass, although this is more difficult for mixtures. An advantage of multiple peaks is the statistical improvement in mass accuracy. Multiple charging allows the m/z range of the mass spectrometer to be modest, even for large proteins. Mass analysers for ESI were mostly quadrupoles and ion traps with m/z ranges of 2000–3000, but orthogonal acceleration TOFs, hybrid quadrupole-TOFs, sector instruments and FTICRs of higher mass range are all available with ESI sources.

MALDI attaches only a single charge or a small number of charges to a peptide or protein; consequently the m/z range for a suitable mass analyser must be much greater. Potentially a linear TOF instrument, with or without a reflectron, has unlimited mass range. Mass separation is based on ion velocity; slower ions take longer to arrive at the detector. Therefore, mass range is limited only by the observation time. In practice, factors such as detector design may inhibit the effective observation of the most massive species, but a mass range of several hundred thousand daltons is attainable.

MS methods for analysing peptides and proteins have two different operating regimes, which can be called low mass and high mass. Low mass describes the range where individual isotopic contributions to the overall molecular ion signal can be resolved as separate peaks. This is 1–2 kDa for a quadrupole of modest performance, perhaps 5 kDa for a high performance MALDI-TOF or ESI orthogonal-acceleration TOF, and significantly higher for FT-ICR. This regime which applies to peptides rather than proteins gives narrow peaks. With internal calibration ‘monoisotopic’ masses can be measured to 5–20 ppm for the ions containing the lowest mass isotopes, including ^1H , ^{12}C , ^{14}N and ^{16}O . Only for the smallest species is this sufficient for an unambiguous isotopic assignment but it frequently differentiates between alternative isobaric species (ions of the same nominal mass). For multiply charged ions, the spacing of adjacent peaks within an isotopic cluster is equal to the reciprocal of the charge ($1/z$); thus z can be determined from a single peak. This is useful for complex spectra with multiple peaks that would otherwise be difficult to

assign. In the high mass regime the isotopic clusters are not resolved and the ‘average’ molecular mass is obtained. Here mass spectrometer resolving power has less effect on overall mass accuracy, although any factor that broadens or distorts peak envelopes will introduce errors. This can include small covalent modifications such as methionine oxidation (+16Da) or addition of a cation such as sodium (+23Da) rather than a proton. These should be clearly resolved for small proteins of perhaps 20 kDa, but not for large proteins of say 100 kDa with inherently broad peaks. The best mass accuracy likely to be achieved with standard instrumentation is approximately 0.1–0.3 Da at 10 000 Da or 1–3 at 100 000 Da.

FT-ICR with a high field magnet represents a divergence from the above statement as this can have extraordinarily high resolving power. **Figure 1** shows the resolved isotopic cluster for the +49 charge state of bovine serum albumin (molecular mass 66.4 kDa), measured with a resolving power of 370 000 using a 11.5 T magnet. Thus, with such an instrument, almost any sample can give isotopic resolution.

Sensitivity of Detection

Soft ionization usually gives molecular ions but not fragment ions; thus ion current is concentrated into a single peak or isotopic cluster. Although the ion yield of the ionization methods is relatively low (~ 1 ion per 1000 neutral molecules), MS is highly sensitive. Less than 100 ions are sufficient to define a mass spectrometric peak, i.e. $\sim 10^5$ molecules or 0.1 attomole. To exploit this inherent sensitivity it is necessary to integrate the entire ion signal, rather than scan a spectrum in which only a small fraction of the ions is monitored while most go unobserved. This is achieved by MALDI-TOF as each laser shot forms a packet of ions which are accelerated into the mass analyser to ultimately arrive at the detector. MALDI also has the advantage that a discrete quantity of sample on the target is available for analysis for as long as the experimenter chooses to select a new region to investigate or until the sample is exhausted, a dried spot from 1 μL of sample being sufficient for several thousand laser shots. By contrast ESI is used mostly with scanning instruments and spectra are recorded during the limited time the analyte enters the ionization region. This is relatively inefficient and ESI has been regarded as less sensitive than MALDI. A newer generation of TOF instruments compatible with ESI integrate the signal, and nanospray is more like MALDI as sample is retained throughout the experiment, providing a substantial sensitivity enhancement. MALDI and nanospray both provide detection limits in the low femtomole region or better.

Additional Techniques

Direct Analysis of Mixtures Versus LC-MS

Because MALDI gives predominant singly charged molecular ions with few fragments, analysis of multi-component mixtures such as protein digests is readily achieved. Each peak corresponds to a separate peptide and can be selected for ‘post-source decay’ or PSD. However, some components in a mixture may not compete effectively for the available charges and may be weak or absent, e.g. tryptic peptides terminating in lysine rather than arginine. ESI is less suitable for direct analysis of mixed peptides as each component gives several multiply charged peaks that cause complex spectra. However, ESI is ideal for LC-MS and is less discriminatory as components elute separately, giving more comprehensive coverage of the original protein. Although unimportant for identification of a protein in a database, this is essential to find protein modifications or mutations. Automation is available from some instrument manufacturers for MS-MS analysis on each molecular species eluting from the chromatograph. Disadvantages of LC-MS include added cost and complexity of the instrumentation and additional time spent equilibrating columns and waiting for components to elute.

Peptide Sequencing by CID

Peptides and proteins can be sequenced by Edman chemistry at levels down to 1–10 pmol, depending on the

number of residues to be determined. This requires a free amino terminus and is ineffective for modified amino acids unless appropriate standards are available. Through the use of CID and tandem mass spectrometers, MS has established itself as a more sensitive, faster alternative to Edman sequencing, although it cannot handle an intact undigested protein. Unlike Edman sequencing, fragment data can be obtained on each component of a mixture without separation. The efficiency of peptide sequencing by MS depends greatly upon the type of instrument available. Tandem mass spectrometers for CID include multisector instruments, triple quadrupoles (QQQs) and hybrid quadrupole-sectors. The less expensive and easier to operate QQQ is widely used. A molecular ion selected in Q1 fragments in Q2 through low energy collisions with a gas, then fragment ions are analysed in Q3. The same experiment, and even MSⁿ, can be carried out in a relatively modest ion trap, or in an FT-ICR with higher resolution but at considerably greater expense. Hybrid QQ-TOFs offer substantially superior performance to QQQs, giving high sensitivity, high resolution data. A MALDI-TOF instrument equipped with a reflectron is equally capable of MS-MS by PSD.

Interpretation of spectra from CID-MS-MS of peptides of up to ~20–25 residues has been well documented. Peptides have a repeating linear backbone with sidechains defining the constituent amino acids. Backbone fragmentation of a singly charged peptide ion gives two species, an ion and a molecule. Retention of the

proton by the *N*-terminal fragment gives an **a**, **b** or **c** ion, whereas *C*-terminal ions are classified as **x**, **y** or **z** (**Figure 2**). The most common cleavage at the amide bonds gives **b** or **y** ions; tryptic peptides with a *C*-terminal basic residue generally exhibit predominant **y** ions. Because ionization occurs by proton addition, this gives an ion with no odd electrons, which can be more stable than a corresponding radical cation. Subsequent cleavage of a backbone bond is associated with transfer of a hydrogen radical to prevent the thermodynamically unfavourable formation of a radical cation and a neutral radical. In forming a **b** ion this hydrogen moves to the neutral, whereas a **y** ion gains one hydrogen in addition to that added during ionization; thus **y** ions are sometimes designated as **y''** or **y** + 2. Ion masses are calculated as the sum of the amino acid residues involved plus 1 H for **b** ions or plus H₃O for **y** ions. Theoretically, cleavage can occur at each amide bond, giving a series of ions defining the amino acid sequence. In **Figure 2**, subscripts attached to the ion types identify which bonds have broken to form the fragment ions, e.g. for a peptide of *n* amino acids, the *C*-terminal ionic fragment formed by loss of the most *N*-terminal amino acid is designated **y**_{*n*-1}. Some ions are formed by further cleavages at the sidechains, giving peaks referred to as **d**, **v** and **w** ions, some of which can identify specific amino acids and differentiate isomeric amino acids such as leucine and isoleucine. The **d** ions represent loss of a group from the

β -carbon of an **a** ion, **w** ions are formed by the equivalent loss from a **z** ion, and **v** ions represent loss of the intact sidechain at the α -carbon of a **y** ion. Multiple bond cleavages also give internal fragments, including individual amino acids that appear in the low mass region of the spectrum as immonium ions $^+\text{NH}_2=\text{CHR}$ that are valuable for diagnostic purposes. Note that **a**₁ is the immonium ion for residue 1.

Interpretation of MS-MS spectra of multiply charged ions from ESI-MS is complicated by the different charge states possible amongst the fragment ions, unless high mass resolution is available. The most comprehensive fragment ion spectra are generally obtained from high energy CID, such as from sector instruments. Programs exist for both the straightforward prediction of spectra and the more difficult interpretation of experimentally obtained spectra.

Chemical Derivatization

Many straightforward chemical reactions can enhance the quality and utility of MS data from peptides and proteins. Before the advent of ESI or MALDI, polar groups in biomolecules were often derivatized to increase volatility, e.g. by permethylation or silylation. This could provide additional information on the number of replaceable hydrogens of a given type. Such procedures are

Figure 2 Collision induced fragmentation scheme for peptides and proteins. The initial ionizing proton is not shown and proton transfers are not shown for backbone cleavages (see text).

still useful. Acetylation with acetic anhydride adds 42 Da for each free amino group, confirming whether the amino terminus is free or blocked, and can distinguish isobaric glutamine from lysine, the latter becoming acetylated. An equimolar mixture of perdeutero and protonated reagent gives double peaks separated by 3 Da for *N*-terminal but not *C*-terminal fragment ions. Esterification with acetyl chloride/methanol adds 14 Da per carboxylic acid and provides similar information about the *C*-terminus and the location of glutamate or aspartate residues. Trypsin digestion in $\text{H}_2^{16}\text{O}/\text{H}_2^{18}\text{O}$ differentially labels the *C*-termini of all resulting peptides, except the original protein *C*-terminus. All of these techniques employing stable heavy isotopes enhance the information content in MS/MS as the *N*- and *C*-terminal fragments are readily distinguishable. Other derivatizations to improve MS/MS spectra include the addition of a permanent positive charge at one or other terminus, usually the *N*-terminus, which directs the fragmentation and aids spectral interpretation.

Protein disulfide bonds can be reduced with dithiothreitol and alkylated with a reagent such as iodo-acetic acid before digestion, adding 58 Da per cysteine. Although MS is replacing Edman sequencing to a significant degree, Edman chemistry is used for ladder sequencing, in which phenyl thiocyanate is included at each cycle with the normal Edman reagent, phenylisothiocyanate. This blocks the *N*-terminus of a small fraction of the analyte molecules and prevents further cleavage, giving mixed products differing from each other by single amino acids. The sequence is read directly from the MALDI spectrum of the unseparated mixture.

Applications

Quality Control of Synthetic Peptides and Recombinant Proteins

MS analysis has become a routine aid in the purification of synthetic peptides and recombinant proteins and plays an essential role in quality control of materials required to be of high purity. Following cleavage from the solid-phase resin, high quality peptides are purified by RP-HPLC. Fractions collected from an analytical run can be surveyed by MS to identify the elution profile of the desired product, with a minimum of impurities. Fractions may be dried down and used directly or they may act as a guide to fraction collection for a larger scale separation. The presence of unwanted side products such as those formed by amino acid deletions, incomplete removal of protecting groups and chemical modifications should be immediately apparent from the measured masses. If careful attention was paid to the sequence of amino acids loaded onto the synthesizer, the observation of the

desired molecular mass should be sufficient to confirm the anticipated product. If necessary, MS/MS can be used to confirm the sequence.

MS and MS/MS are particularly useful for identifying and locating heavy isotopes. For example, **Figure 3** shows a portion of the MS/MS spectrum of three versions of a 14-residue peptide prepared for an NMR study, two of which contain ^{13}C labels at a carbonyl and an α -carbon in two alanine residues. Mass differences between successive **a** and **b** ions allow the positions of these residues to be determined precisely. As **b**₆ is at m/z 656 for all three species including the unlabelled control, no ^{13}C labels are present in the first six residues. However, **a**₇ for compound (c) is 1 Da higher than the equivalent ion for (a) or (b); therefore the α -carbon of the seventh residue in (c) is ^{13}C . Similar logic allows each of the other labels to be identified.

A number of potential chemical modifications can cause recombinant proteins to differ from the desired product. Cysteine-containing proteins may show a time-dependent shift of both chromatographic retention time and mass as aerobic oxidation causes disulfide formation (−2Da per disulfide). Methionine oxidation to the sulf-oxide is quite common and is readily identified (+16Da). *N*-terminal glutamine may eliminate ammonia to form pyroglutamic acid (−17Da), especially if stored in acidic solution. Harder to detect may be deamidation of asparagine to form a succinimide intermediate that is then hydrolysed to aspartate, or its isomer isoaspartate (+1Da). Posttranslational modifications such as glycosylation occurring in mammalian systems are rarely observed in proteins expressed in bacteria but processes such as phosphorylation are not unknown. Enzyme impurities from the expression system may be responsible for numerous reactions, including the total degradation of the desired product. Carboxypeptidases and aminopeptidases can result in unexpected trimming of the intact sequence. *N*-terminal methionine is quite often observed to be partly or completely absent (−131 Da). This list of potential variants is far from complete but it gives an indication of the role that MS can play in their identification.

Protein Identification by In-Gel Digestion and Database Searching

Early in the 21st century, the completion of the sequencing of the human genome was achieved along with those of number of other organisms. This effort yielded a vast array of information about genes, but this turned out to be the tip of the iceberg compared with the unanswered questions relating to proteins, including cellular and tissue-specific variations in levels of expression, posttranslational modifications, and their associations to form functional multimolecular units. MS is playing an

Figure 3 Partial CID-MS/MS spectrum obtained on a tandem 4-sector mass spectrometer for a 14-residue synthetic peptide. (a) without ¹³C labels; (b) and (c) with ¹³C labels as indicated by asterisks.

essential role in the elucidation of this information, now referred to as proteomics, and this is the subject of a separate article in this encyclopedia. Techniques are now available for the analysis of the major proteins in specific cell types. At present the most productive methods link 2D electrophoresis with high sensitivity MS and database searching, sometimes referred to as 'mass fingerprinting'.

As many as 2000 proteins from a cell digest may be separated on a 2D gel as discrete spots stained with Coomassie blue (100 ng sensitivity), silver (1–10 ng) or a fluorescent dye (<1 ng). These proteins can be difficult to elute from the gel in high yield for direct analysis by MS. Furthermore, if it could be determined, even the precise atomic composition would be insufficient information to identify a protein. However, cutting the spot from the gel, digesting the protein with an enzyme such as trypsin, eluting the peptides and analysing them by MS can provide sufficient information to unambiguously identify any known protein in a standard protein database, particularly if ion masses are measured accurately. Tryptic peptides are advantageous as they all terminate in a readily protonated basic residue, lysine or arginine. They can either be analysed in the intact mixture, usually by MALDI or nanospray, or separated and analysed by LC-MS. Software is freely available for database searches. As yet the databases are incomplete and many proteins remain unidentified, but ultimately all possible proteins will be predictable for an entire genome. As databases increase in size it will become necessary to increase the

number of peptides identified or further improve the accuracy of mass measurement. Alternatively, sequence information from CID and MS/MS will greatly increase the reliability of identification.

Identification of Genetic Mutations

Most genetic mutations are identified by molecular biological techniques including gene sequencing. However, mass spectrometry of protein digests was a valuable additional method even before the development of ESI and MALDI. The molecular mass of an intact protein can now be determined by ESI or MALDI, which compared with a normal protein or the predicted sequence from a c-DNA will indicate the presence of a mutation. The precise location and identity can be confirmed by digestion and further analysis of the peptides by LC/MS or LC/MS/MS. The identification of haemoglobin variants represents one of the best known examples of mutational analysis by MS. Most patients are heterozygous, i.e. blood samples contain both the normal and variant forms of the protein. With a molecular mass in the region 15–16 kDa, monomeric haemoglobin is a relatively small protein and the differences between normal and variant forms are easily measured with high precision. Mass spectrometry complements the normal electrophoretic detection of the numerous haemoglobin variants responsible for a number of serious diseases including sickle-cell anaemia.

Posttranslational Modifications
